Abstract

Introduction: In search for a suitable rat model to study potentially affected blood-brain barrier (BBB) transport mechanisms in the course of Parkinson’s disease (PD) progression, experiments were performed to characterise Parkinson’s disease markers following subcutaneous (SC) and intracerebral (IC) infusion of the toxin rotenone in the rat. Methods: Studies were performed using Male Lewis rats. SC infusion of rotenone (3 mg/kg/day) was performed via an osmotic minipump. IC infusion of rotenone occurred directly into the right medial forebrain bundle at three different dosages. At different times following rotenone infusion, behaviour, histopathology (tyrosine hydroxylase and alpha-synuclein immunocytochemistry), peripheral organ pathology (adrenals, heart, kidney, liver, lung, spleen and stomach) were assessed. In part of the SC and IC rats, BBB transport profiles of the permeability marker sodium fluorescein were determined using microdialysis. Results: SC rotenone failed to produce dopaminergic lesions and led to extensive peripheral organ toxicity. BBB permeability for fluorescein following SC rotenone was changed, however due peripheral toxicity. In contrast, IC rotenone produced a progressive lesion of the nigrostrial dopaminergic pathway over 28 days with no associated peripheral toxicity. IC rotenone also exhibited a large increase in amphetamine induced rotational behaviour. In addition, a few IC rats showed alpha-synuclein immunoreactivity and aggregation. Following IC rotenone, no changes in BBB permeability were detected after 14 days. Discussion: SC rotenone only produced peripheral toxicity. IC rotenone appeared to create a progressive lesion of the rat nigrostrial pathway, and may therefore be a more appropriate model of Parkinson’s disease progression, compared with the most commonly used 6-OH-DA rat model.

1. Introduction

Parkinson’s disease is a chronic, progressive neurodegenerative disease in which nigrostriatal dopaminergic neurones are gradually lost, leading to a decrease in dopamine concentration in the striatum (Dauer & Przedborski, 2003). It is the second most common neurodegenerative disease and its current therapy focuses mainly on symptomatic treatment by replacing the loss of dopamine in the striatum (Mercuri & Bernardi, 2005) by L-Dopa, the dopamine precursor. The most recent discoveries in the fields of diagnosis and treatment of Parkinson’s disease have recently been reviewed (Savitt, Dawson, & Dawson, 2006). The main goal for future treatment of Parkinson’s disease is the discovery and development of neuroprotective/neurotrophic drugs to diminish or, better, to halt the disease progression (Bonuccelli & Del Dotto, 2006; Chen &
An important consideration for the development of neuroprotective drugs for the treatment of Parkinson’s disease is the relationship between disease progression and the pharmacokinetic and pharmacodynamic (PK–PD) properties of the drug.

In the PK–PD relationship of anti-Parkinsonian drugs a number of factors are of importance. One factor is transport of the drug across the blood-brain barrier (BBB). Drug transport is governed by a number of BBB transport mechanisms (de Boer, van, & Gaillard, 2003). Passive transport across the BBB occurs by simple diffusion, either paracellularly or transcellularly across the cerebral capillary endothelial cells that compose the BBB. For hydrophilic solutes the diffusion via the paracellular transport route is highly impeded by the presence of the tight junctions between the brain capillary endothelial cells. Besides, many active influx and efflux transport mechanisms are present at the BBB. For example, active efflux transport by P-glycoprotein (Pgp) or the multidrug resistance protein (MRP) as has previously been shown for numerous compounds (de Lange et al., 2000; Schinkel, Wagenaar, Mol, & van Deemter, 1996; van, et al., 2001; Vautier et al., 2006) for reviews see (Borst, Evers, Kool, & Wijnholds, 2000; Gottesman, Fojo, & Bates, 2002; Loscher & Potschka, 2005; Schinkel, 1999).

BBB functionality is dynamically controlled by blood components and the surrounding brain cells by direct contact or indirectly by their extracellular products. Thus, BBB functionality may vary among different physiologic, pathologic, and chronic drug treatment conditions. It should be realised that BBB transport of a particular drug into and out of the brain is the sum of all actual BBB transport mechanisms applicable to that particular drug, and that changes in BBB transport mechanisms by the disease state may therefore affect BBB transport of the drug. PK–PD relationships of symptomatic drugs such as levodopa (l-Dopa) in patients with different stages of Parkinson’s disease have been described previously (Chan, Nutt, & Holford, 2005; Harder & Baas, 1998) and indicate that Parkinson’s disease progression is able to influence PK–PD parameters of anti-Parkinsonian drugs. Moreover, in a clinical study from 2005, Parkinson’s disease was associated with a reduction in Pgp (Kortekaas et al., 2005). Carvey et al. (2005) found an increased leakage of the BBB in 6-hydroxydopamine (6-OH-DA) lesioned rat, indicated by the leakage of FITC-labeled albumin or horseradish peroxidase from the vasculature into the parenchyma, in both the striatum and substantia nigra (SNC) after 6-OH-DA injection. Furthermore, it has been shown that blood to brain transport of L-Dopa is reduced in the 1-methyl-4-phenyl-1,2,3,6-tetrahydroprydine (MPTP) Parkinsonian monkeys (Alexander, Schwartzman, Grothusen, & Gordon, 1994a) implicating changes in the BBB, as caused by the diseased state of the animal specifically to the large amino acid transporter.

It is important to reveal in which direction and to what extent the different BBB transport mechanisms (and actual BBB transport of a drug) are influenced by Parkinson’s disease progression. This should be addressed in a systematic manner, in relation to the physico-chemical properties of the drug. To that end preclinical studies are needed using an adequate animal model of Parkinson disease in which Parkinson disease progression can be identified. The most widely used animal models of Parkinson’s disease are neurotoxin models where MPTP (mice, cats and primates) or 6-OH-DA (mice, rats, cats and primates) are used (Beal, 2001). These models are generally acute (Betarbet, Sherer, & Greenamyre, 2002; Schober, 2004), but in some cases MPTP subchronic models in both primates and mice have been used (Schober, 2004). Recently, a mouse Parkinson’s disease model was introduced in which MPTP was continuously administered through an osmotic minipump (Fornai et al., 2005). This models appears to have the advantage over the other MPTP models that there is formation of inclusion bodies in the SN. Although these data look very promising, it has not yet been described elsewhere. An intrastriatal injection of 6-OH-DA seems to also show a more progressive degeneration of nigral dopaminergic cells compared to intranigral injections or injections into the median forebrain bundle (MFB) (Cicchetti, Brownell, Williams, Chen, Livni, & Isacson, 2002; Sauer & Oertel, 1994). However, no Lewy body formation has yet been observed in any of the 6-OH-DA models. Other approaches, which have extensively been reviewed elsewhere (Betarbet et al., 2002; Uversky, 2004) include the genetic models of Parkinson’s disease and the use of reserpine, methamphetamine, 3-nitrotyrosine paraquat in combination with maneb and rotenone to induce Parkinson-like symptoms. The subcutaneous (SC) infusion of rotenone to induce Parkinson’s disease in the rat neurons has been reported, in which a gradual increase in striatal dopaminergic denervation with associated alpha-synuclein-positive cytoplasmic inclusions in nigral (Betarbet et al., 2000; Sherer, Kim, Betarbet, & Greenamyre, 2003). Most recently, the intracerebral (IC) infusion of rotenone into the MFB or SNC has been reported to affect the nigrostriatal pathway and produce deficits which were reversed by l-Dopa (Alam, Mayerhofer, & Schmidt, 2004; Antkiewicz-Michaluk et al., 2004; Saravanan, Sindhu, & Mohanakumar, 2005; Sindhu, Saravanan, & Mohanakumar, 2005).

In this study we have first investigated the influences of SC administration of rotenone (3 mg/kg/day) via an osmotic minipump in the rat on bodyweight and behaviour (locomotor activity) as measured frequently within a period of 4 weeks. Within this period, at different time intervals, rats were sacrificed and brains were used to assess nigrostriatal damage based on immunohistological staining on tyrosine hydroxylase, while in addition for all rats peripheral organ pathology was determined. In a separate experiment, at 14 days of SC administration of rotenone–BBB permeability was assessed using sodium fluorescein as a marker. In a last experiment, peripheral organ pathology was performed to determine the effect of 3 mg/kg/day rotenone systemically. In a subsequent series of experiments, the influence of IC administration of rotenone in the MFB at three different doses of rotenone (0.5, 2.0 and 5.0 μg) on nigrostriatal damage (immunohistological staining on tyrosine hydroxylase) was determined. To be able to compare these results to the results obtained in the experiments using the subcutaneous rotenone model, we carefully monitored bodyweight and peripheral organ pathology was also performed on these rats. After confirming we were producing a suitable lesion we used the highest rotenone dose (5.0 μg) in behavioural experiments and in a microdialysis experiment using sodium fluorescein as a BBB permeability marker. A summary of all the experiments which are presented in this paper is shown in Table 1.
2. Materials and methods

2.1. Statement on use and care of animals

The experiments described in this paper were approved by the Ethical Committee on Animal Experimentation of the University of Leiden (DEC numbers 118 and 5069).

For all experiments (Table 1) inbred adult male Lewis rats (250–300 g, Charles River BV, Maastricht, The Netherlands) were used. The rats were housed in standard plastic cages (six per cage before surgery and individually after surgery) with a normal 12-hour day/night schedule (lights on 7:30AM) and a temperature of 21 °C. The animals had access to standard laboratory chow (RMH-TM; Hope Farms, Woerden, The Netherlands) and acidified water ad libitum.

2.2. Surgical methods

2.2.1. Placement osmotic minipumps

In these experiments, the rats were implanted with an Alzet osmotic minipump (2ML-4, Alzet CR, Maastricht, The Netherlands) placed subcutaneously on the back of the rat. For the rats in the microdialysis experiment, the pump was placed 7 days after microdialysis surgery. The osmotic minipump was filled with either 3 mg/kg/day Rotenone (Pestanal®, Sigma Aldrich BV, Zwijndrecht, the Netherlands) dissolved in a 1:1-mixture of dimethylsulfoxide (DMSO, Sigma Aldrich BV, Zwijndrecht, the Netherlands) with polyethylene glycol (PEG 200, Sigma Aldrich BV, Zwijndrecht, the Netherlands) as the vehicle (DMSO:PEG; 1:1), or filled with the vehicle alone or saline (0.9% NaCl). Pumps were incubated in sterile saline at 37 °C overnight. For the implantation, rats were deeply anesthetised using isoflurane (Forene®, Abbott B.V., Hoofddorp, The Netherlands). The Alzet osmotic minipumps were implanted under the skin on the back of the rat. The rats were weighed on regular basis to monitor general well-being. Rats were euthanised either after 7, 14, 21 or 28 days or after the development of hunched posture suggestive of abdominal pain and upon inadequate feeding or grooming, suggestive of ongoing toxicity.

2.2.2. Implantation of blood cannulas

The surgery for the microdialysis study was performed under anesthesia with an intramuscular injection of 0.1 mg/kg medetomidine hydrochloride (Domitor 1 mg/ml, Pfizer, Capelle a/d IJssel, The Netherlands) and 1 mg/kg ketamine base (Ketalar 50 mg/ml, Parke-Davis, Hoofddorp, The Netherlands). Two indwelling cannulas (pyrogen-free, nonsterile polyethylene tubing, Portex Limited) were implanted, one in the left femoral artery and one in the left femoral vein. The cannula in the left femoral vein was used for administration of fluorescein.

whereas the cannula in the left femoral artery was used for serial collection of arterial blood samples. The cannulas were tunneled subcutaneously and fixed at the back of the neck with a rubber ring. The skin in the neck was stitched with normal sutures. The skin in the groin was closed with wound clips. To prevent clotting and cannula obstruction, the cannulas were filled with a 25% (w/v) polyvinylpyrrolidone solution (PVP; Brocacef, Maarssen, The Netherlands) in pyrogen-free physiological saline (B. Braun Melsungen AG, Melsungen, Germany) containing 20 IU/ml heparin (Hospital Pharmacy, Leiden University Medical Center, Leiden, The Netherlands). After the implantation of the cannulas, the rats were placed in a stereotaxic frame and the skull was exposed for brain surgery.

2.2.3. Microdialysis surgery for the subcutaneous model

After the implantation of the cannulas, a small hole was drilled to allow the implantation of a microdialysis guide cannula (CMA/12, Aurora Borealis Control B.V. Schoonebeek, The Netherlands) in the striatum (relative to bregma (Paxinos, Watson, Pennisi, & Topple, 1985): AP:+0.4; L:+3.2; V:–3.5). Two support screws were placed to hold the guide, which was glued to the skull with dental acrylic cement (Howmedia simplex rapid + methacrylate, Drijfhout, Amsterdam, The Netherlands). The osmotic minipump was placed 7 days after the microdialysis surgery and the experiment was carried out 14 days after pump implantation.

2.2.4. Microdialysis surgery for the intracerebral model

After the implantation of the cannulas, the rats received a unilateral infusion into the right MFB (AP:–2.8; L:+2.0; V:–9.0 relative to bregma; Paxinos et al., 1985) at a rate of 0.1 μl/min for 30 min of either vehicle (DMSO/PEG, 1:1; n=8; referred to as sham) or 5.0 μg of rotenone (n=12). After the infusion, the needle was kept in place for another 5 min to allow diffusion of the fluid without leakage along the track of the needle. Subsequently, two small holes were drilled into the skull to allow implantation of a microdialysis guide cannula (CMA/12, Aurora Borealis Control B.V. Schoonebeek, The Netherlands) in the left and in the right striatum relative to bregma (AP:+0.4; L:+3.2; V:–3.5, relative to bregma; Paxinos et al., 1985). One support screw was placed as an extra anchor for fixation of the guide, which was glued to the skull with dental acrylic cement (Howmedia simplex rapid + methacrylate, Drijfhout, Amsterdam, The Netherlands). The microdialysis experiment was carried out 14 days after microdialysis surgery.

2.3. Experimental methods

2.3.1. Subcutaneous model: Behavioural experiment

For this study (in total n=108), the rats received an Alzet osmotic minipump filled with either rotenone in vehicle (n=60, for a dose of 3 mg/kg/day), vehicle alone (n=24), or saline (n=24). For each treatment, the rats were divided into 4 groups with different treatment durations of respectively 4, 14, 21 and 28 days after which the rats were given an overdose of Nembutal® (Natriumpentobarbital 60 mg/ml, Ceva Sante Animale,
Fig. 2. Illustrates the influence of either subcutaneous administration or intracerebral administration on the behaviour in the rat. The effect of different doses of rotenone (n=8 per dose and per timepoint) and artificial ECF (n=8 per timepoint) infused into the MBF on the percentage (lesioned vs. intact brain side) striatal TH immunostaining in time. The data are presented as mean values±SEM.

Naaldwijk, The Netherlands) and the thorax was opened and the rat was perfused with 30 ml of saline followed by 30 ml of 10% phosphate buffered formalin (pH=7.0) via the left ventricle of the heart. Brains were removed for histopathology. During the entire course of the experiment, the bodyweight of the rats was monitored daily from Monday to Friday (Table 1). Before implantation of the minipump, the rats were trained daily for 2 weeks on the Rotarod (Ugo Basile, Comerio, Italy). After implantation, the rats’ ability to stay on the Rotarod was tested on a daily basis during the week, in two sessions. Before the first session the rat was weighed, and then placed on the drum of the Rotarod with the head facing in the direction opposite to the direction of rotation. This forced the rat to move forward in order to stay on the rotating drum. The drum was started at a speed of 2 rotations per minute (r.p.m) and accelerated every 30 s to a final maximum speed of 20 r.p.m. after 5 min. At this time, the session was ended and the rat was allowed to recover for a 30 min period before the second session was started. As a behavioural read-out, the time that the rat was able to stay on the drum was recorded. All rats that were unable to remain on the Rotarod for at least 250 s before the start of the treatment were excluded from data analysis.

2.3.2. Intracerebral model: Behavioural experiment

For this study, male Lewis rats received a unilateral infusion into the MFB of either DMSO/PEG (1:1; n=8; vehicle) or 5.0 μg of rotenone (n=12). Approximately 21 days after rotenone infusion the animals were placed in automated rotometers (Med. Associates Ltd.). The apparatus consisted of perspex bowls where each rat was linked to a harness carrying an infrared sensor at the top connected to a computer with ROTORAT software. The animals were tested for rotations in absence (baseline) and in the presence (stimulation) of amphetamine (5 mg/kg i.p.) to evaluate the effects of rotenone treatment on stimulant-induced rotations. On the day of sacrifice (day 28), the animals were given an overdose of anaesthetic and the thorax was opened and perfused with 30 ml of saline followed by 30 ml of 10% phosphate buffered formalin (pH 7.0) via the left ventricle of the heart. Brains were removed for histopathology.

2.3.3. Subcutaneous and intracerebral model: Microdialysis experiment

At 18–24 hours prior to the experiment, the microdialysis probes (CMA12, membrane length of 4.0 mm; Aurora Borealis Control B.V. Schoonebeek, the Netherlands) were gently inserted into the guide cannulas after removal of the probe dummies. The microdialysis experiment was started between 7:00 and 8:00 a.m. The inlets of both microdialysis probes were connected by FEP tubing (fluorinated ethylene propylene tubing; internal volume of 1.2 μl/100 mm length; Aurora Borealis Control B.V. Schoonebeek, the Netherlands) to syringe pumps (Beehive, Bas Technicol, Congleton, United Kingdom). The probes were perfused with aECF (composition in mM: NaCl 145; KCl 2.7; CaCl2 1.2; MgCl2 1.0; ascorbic acid 0.2 in a 2 mM phosphate buffer pH 7.4; Moghaddam & Bunney, 1989) at a flow rate of 2 μl/min. The outlets consisted of fused silica tubing (I.D. 150 μm, O.D. 375 μm; Composite Metal Services Ltd, ilkley, United Kingdom) and were connected to a microsample collector (Univentor 820; Antec, Leiden, The Netherlands), in which the samples were collected and cooled (4 °C). After a stabilization period of 60 min, the in vivo recovery of fluorescein was determined by the retrodialysis method. For this purpose, the probes were first perfused with a fluorescein solution (10 or 20 ng/ml in aECF) for 60 min to collect 6 fractions. The relative loss of fluorescein was calculated as an average of this period. After this period, the syringes were switched to blank aECF for the washout phase of 90 min. After the washout period, the intravenous administration of fluorescein was started. The venous cannula was connected to a syringe containing fluorescein (Sigma Aldrich BV, Zwijndrecht, the Netherlands) in saline (0.9% NaCl). For a dose of 6 mg/kg of fluorescein, a 2-minute intravenous infusion was started at a rate of 50 μl/min. In the first 120 min of the experiment, microdialysis fractions were collected at 10-minute intervals and from 120–180 min from

180–240 min at 20- and 30-minute intervals, respectively. Blood samples (50 μl in heparinised Eppendorf vials) were taken at 0, 0.5, 2, 4, 6, 8, 10, 15, 20, 25, 30, 45, 60, 90, 120, 180 and 240 min after start of the fluorescein infusion. The blood samples were centrifuged for 10 min at 5000 r.p.m. and the plasma was pipetted into Eppendorf vials. All samples were stored at −20 °C.

2.4. Subcutaneous and intracerebral model: Histopathology

TH immunohistochemistry was performed to quantify the degree of dopaminergic neurodegeneration. In short, the brains were cut twice into 6-mm segments using a rodent brain matrix, processed, and embedded in paraffin wax. Coronal sections (8 μm) were cut through the striatum (at 1.2 mm caudal to bregma) and the SNc (from −4.5 to −6.2 mm caudal to bregma) (Paxinos et al., 1985) with a sledge microtome (Microm, Walldorf, Germany). The sections were deparaffinised and rehydrated and endogenous peroxidase was quenched with 0.3% H2O2 for 30 min. The slides were placed in pepsin (0.2 g of Sigma-p-7000 pepsin in 50 ml of 0.01 M HCl) for 30 min, washed, and non-specific binding was blocked with 1.5% normal goat serum (Vectastain rabbit IgG ABC kit; Vector Laboratories, Burlingame, CA). This was followed by the application of the primary rabbit polyclonal anti-tyrosine hydroxylase antibody (AB152 incubated for 18 h at room temperature; Chemicon International, Temecula, CA), the secondary biotinylated antibody (Vectastain rabbit IgG ABC kit for 30 min) and the horseradish peroxidase conjugate (Vectastain rabbit IgG ABC kit for 30 min). Visualisation was carried out using 3,3′-diaminobenzidine (Vector SK-4100 Vector Laboratories, Burlingame, CA) as a chromogen. The slides were coverslipped using DPX mountant. Adjacent nigral sections were immunostained for alpha-synuclein using a anti-alpha-synuclein (1:200, AB15530, Abcam, UK).

After staining, striatal sections were scanned using SprintScan 35 with PathScan Enabler™ at a resolution of 1012 dpi. Optimas 5.2 software was used to measure the optical density of manually-defined areas of each black and white image produced as a mean grey value (MGV). TH-IR was measured for the slide (background), cortex (control tissue staining), corpus callosum (control non-cellular staining), dorsal striatum (caudate putamen, CPu) and ventral striatum (nucleus accumbens, NAcc). The values were adjusted for non-specific staining by subtracting the MGV of the corpus callosum or cortex, an area that should have no specific TH staining. Values obtained were entered into a spreadsheet sorted by treatment group, and the

Fig. 3. A Intracerebral rotenone model: Images of tyrosine hydroxylase immunostaining of coronal sections taken at the level of the striatum from aECF (a) or rotenone-infused rats (0.5 (b), 2.0 (c) or 5.0 (d) μg) taken 14 days after infusion. Each treatment group is represented by 4 rats, the left striatum represents the intact side of the animal and the right striatum represents the lesioned side of the same animal. The lowest (b) and middle (c) rotenone doses show partial dopaminergic denervation whereas the highest rotenone dose (d) had more pronounced loss in staining and some rats had almost complete dopaminergic denervation. B: Intracerebral rotenone model: Images of tyrosine hydroxylase staining at the level of the substantia nigra form aECF (a) or rotenone-infused rats (0.5 (b), 2.0 (c) or 5.0 (d) μg) on day 14 after infusion. The left hand images show the intact substantia nigra with higher magnification of the cell bodies as insets. The right hand side shows the lesioned side of the brain with insets showing a higher magnification of the cell bodies. There is a clear dose-dependent loss in TH positive cells and processes (see arrows) with increasing concentrations of rotenone.
mean, standard deviation and standard error (SEM) calculated using formulas. These means and errors were subsequently plotted and unless otherwise stated, all striatal TH-IR values are corrected for cortical TH-IR.

A series of sections through the SN (−4.5 mm to 6.2 mm) were evaluated and stained. After careful evaluation under the microscope the TH positive cells within the SNc were counted at one selected stereotaxic level (−5.2 to 5.4 mm caudal to bregma) in both vehicle-treated and the rotenone-lesioned animals. The cells were counted manually using a digital camera (Hitachi HV-C20A) attached to a light microscope (LEICA DMLB, Leica Microsystems Wetzlar GmbH) at × 20 magnification and the lesioned side is expressed as a percentage of the intact side. Light microscopy was also used to provide a
qualitative assessment of the presence of alpha-synuclein in the SNc in the intracerebral experiment.

2.5. Subcutaneous and intracerebral model: Peripheral organ pathology

The pathological evaluation of the brain and peripheral organs of the subcutaneous experiment was performed on 56 rats and of the intracerebral experiment on 96 rats (Table 1). After 7, 14, 21 or 28 days of treatment (for the subcutaneous experiment only 14 or 28 days), the animals were given an overdose of Nembutal® (Natriumpentobarbital 60 mg/ml, Ceva Sante Animale, Naaldwijk, The Netherlands) and the thorax was opened and the rat was perfused with 30 ml of saline followed by 30 ml of 10% phosphate buffered formalin (pH=7.0) via the left ventricle of the heart. Adrenals, heart, kidney, liver, lung, spleen and stomach were removed and immersed in 10% neutral buffered formalin (pH=7.0), trimmed after adequate fixation according to a

Fig. 4. Intracerebral rotenone model: Examples of alpha-synuclein positive staining in the SNc of rats that have received 0.5 μg (C and D), 2 μg (E and F) or 5 μg (G and H) rotenone or aECF (A and B) into the left medial forebrain bundle (MFB, stereotaxic coordinates: AP:−2.8, Lat:+2.0, V:−9.0) and killed off 28 days post surgery. Both the intact SNc (A, C, E and G) and the lesioned SNc (B, D, F and H) are shown at 20× magnification. Alpha-synuclein staining was visualised with 3-6-diaminobenzidine (DAB) with a haematoxylin counter stain.
standard operating procedure inspired from the Registry of Industrial Toxicology Animal-data (RITA) standards (Bahne-
mann et al., 1995), and appropriate samples routinely processed to
tissue blocks embedded with paraffin wax. Tissue sections were
cut at approximately 3 μm, stained with Harris' haematoxylin and
eosin (HE), Oil red O for neutral fat and Von Kossa's stain for
mineral/calcium deposits and examined by light microscopy for
relevant changes by a pathologist, without knowledge of the
treatment status.

2.6. Subcutaneous and intracerebral model: Analysis of fluorescein

The plasma and microdialysate samples obtained in the
subcutaneous model experiment were analysed for fluorescein
concentrations by HPLC with fluorescence detection. The
HPLC system comprised a PSS Suprema size exclusion column
(8×300 mm, 10 μm particle size), with a mobile phase of
0.05 M ammoniumacetate (pH =9.0) and acetonitrile (4:1 v/v).
The flow rate was maintained at a flow of 1.5 ml/min. The
detection was performed using a fluorescence detector (LC240,
Perkin Elmer, United Kingdom) with the excitation wavelength
set at 488 nm and the emission wavelength set at 512 nm. The
microdialysate samples (15 μl) were injected directly onto the
HPLC column. For the analysis of the plasma samples, 10 μl of plasma was added to 990 μl of an icecold artificial extracellu-
lar fluid (described above) and vortexed for 10 s. A 50 μl aliquot
of this mixture was injected directly onto the HPLC system
equipped with a refill guard column (2 mm I.D.×20 mm)
(Upchurch Scientific, Oak Harbor, WA, USA) packed with C18
(particle size 20–40 μm) (Altech, Breda, The Netherlands).

For the analysis of fluorescein in plasma and microdialysate
samples from the intracerebral experiment, we developed an
assay using the Fluostar Optima, which was a fast and reliable
method. The results of the validation of this assay are presented
in Table 2. The detection limit was 0.08 ng/ml. For the analysis
of the microdialysate samples, 10 μl microdialysate was
pipetted onto a black 96-well plate (FIA-plate flat bottom/
medium binding, Greiner, Alphen a/d Rijn, The Netherlands)
and 40 μl of a 0.25 M NaOH solution was added. For the
analysis of the plasma samples, an aliquot of 10 μl plasma was
pipetted onto a black 96-well plate and 90 μl of a 0.1 M NaOH
solution was added. The fluorescence intensity was measured
on the Fluostar Optima (BMG Labtech, Offenburg, Germany) at
the emission wavelength of 530 nm and the excitation wave-
length of 480 nm.

2.7. Statistical analysis

All data were statistically evaluated for significance by one-
way analysis of variance (ANOVA) and a Tukey–Kramer mul-
tiple comparison test except for the microdialysis fluorescein data
from the subcutaneous experiment which were evaluated using
Student's t-test due to the small sample size of the saline and
vehicle groups. Values of $P<0.05$ were considered significant.

Fig. 5. Intracerebral rotenone model: Examples of possible alpha-synuclein overexpression (o) and aggregation (a) in dopaminergic cells compared to non-expressing
cells (n) within the SNc of rats with rotenone-induced lesions of the MFB. Images are at 100× magnification, alpha-synuclein was visualised with DAB and a
haematoxylin counterstain.
3. Results

3.1. Subcutaneous model: Bodyweight and locomotor activity

The subcutaneous infusion of rotenone produced a time-related reduction ($P \leq 0.001$) in bodyweight of rotenone-treated rats, compared with vehicle- or saline-treated rats (Fig. 1A). This reduction was most pronounced in the first 10–14 days following the start of the treatment. Behavioural analysis using the Rotarod was performed at various timepoints after infusion of saline, vehicle or rotenone (Fig. 2A). The analysis was based on the time-period in which the rat was able to remain on the Rotarod (latency time). Results were categorised into 3 panels; panel 1 for latency times ranging between 0 and 100 s, for panel 2 between 100 and 200 s, and for panel 3 between 200 and 300 s. In saline-treated rats and vehicle-treated rats only 2–3% of the animals had a Rotarod latency lower than 100 s whereas in rotenone-treated rats this number had increased to 30% (panels A1, B1, C1). Also, 77% of the saline-treated rats and 86% of the vehicle-treated rats were able to stay on the apparatus for more than 200 s, but only 45% of the rotenone-treated rats were able to stay on the Rotarod for that period of time (panels A3, B3, C3). Therefore, rotenone treatment impaired Rotarod performance, with a greater percentage of these animals falling off the apparatus at early timepoints and fewer animals staying on for the full testing period (300 s).

3.2. Intracerebral model: Bodyweight and rotational behaviour

The effect of the intracerebral infusion of either aECF, 0.5 μg rotenone, 2.0 μg rotenone or 5.0 μg rotenone into the MFB on the body weight of the rat (Fig. 1B) indicated that there was a decrease in body weight of about 10–15% in all treatment groups in the first 2 days after surgery. However, from 2 days onwards until the end of the experiment (day 28) the body weight increased as normal in all treatment groups and overall there were no statistically significant differences among the various treatment groups. In agreement with this, the experimenter’s observations of the rats with regard to grooming indicated no noticeable differences among control rats and rotenone-treated rats. To determine the behavioural consequences of intracerebral infusion of rotenone, we performed an experiment in which we measured amphetamine (5 mg/kg i.p.) induced rotations in rats infused with 5.0 μg of rotenone and compared these results to sham (=DMSO/PEG; 1:1) infused rats (Fig. 2B). The left panel depicts the mean total rotation score and the right panel illustrates the time course of the rotations for both the sham infused rats and the rotenone-infused rats. The baseline of both groups, measured before the injection of amphetamine, shows no preference of any group for a particular side. However, after the amphetamine challenge the rotenone-infused had a large and significant increase in the number of ipsiversive rotations.

3.3. Histopathology

3.3.1. Subcutaneous model

Looking at the individual subcutaneous rotenone rat model data from the behavioural and microdialysis experiments, only 2% of the rotenone-treated rats showed any loss of tyrosine hydroxylase staining in the striatum. The loss of striatal staining in these particular rats showed a similar pattern to that reported by Betarbet et al. (2000). No loss of cell bodies in the SNc of any animals in the present studies was observed. The mean data for the striatum and SNc are shown in Tables 3 and 4, respectively. No significant difference was seen in the mean striatal TH immunostaining of control, vehicle and rotenone-treated rats or in the mean number of TH positive cells in the SNc among these groups.

3.3.2. Intracerebral model

The histological evaluation of the intracerebral infusion of rotenone indicated that there was no effect of the aECF infusion on the percentage of striatal TH immunostaining (Table 3 and Fig. 3A), while there was a dose-dependent decrease in TH staining in rats with rotenone infusion. The dose-dependent nature of the toxin effect was most pronounced on day 14 after infusion. However, while the damage appeared to be progressive, there were no significant differences among any of the rotenone doses on day 28 compared to day 14 and a time-dependent decrease can only be observed for the 5.0 μg rotenone dose. Also, there appears to be an increase in TH staining in both the striatum and SNc for the 2.0 μg dose between day 14 and 28. The TH immunostaining of the SNc (Table 4 and Fig. 3B) showed that aECF infusion did not alter the number of TH positive nigral cells, but infusion of rotenone produced a dose-dependent decrease in cell number, although less pronounced than that observed in the striatum.

Fig. 6. Subcutaneous rotenone model: A: Limiting ridge of the stomach, Lewis rat given 3.0 μg/day of rotenone for 28 days. The muscularis and submucosa have extensive mineralisation (arrow), haematoxylin and eosin (HE) stain. Original magnification 100×. B: Serial section of the change observed in Fig. 6A stained according to von Kossa’s method for calcium precipitates (arrow). Original magnification 100×. C: Right ventricular free wall of the myocardium, Lewis rat given 3.0 μg/day of rotenone for 14 days. Minimal focus of myocardial necrosis (arrowheads) and adjacent perivascular mononuclear cell infiltration. HE. Original magnification 400×. D: Median lobe of the liver of a Lewis rat given 3.0 μg/day of rotenone for 14 days. Slightly increased single cell necrosis (inset) and slight inflammation (aggregates of mixed cells — arrow) are observed in numerous centrilobular areas adjacent to the central veins (CV), along with slight diffuse cytoplasmic hepatocellular vacuolation (arrowheads). Occasional focal widening of the perivenous centrilobular spaces suggests loss of centrilobular hepatocytes. HE. Original magnification 100×. E: Median liver lobe from a Lewis rat given saline for 14 days. Clear cells with empty spaces (interpreted as washed-off glycogen storage) and a few vacuolation (interpreted as lipid droplets) typical of normal liver of a non-fasted rat. CV: central vein. PV: portal vein. HE. Original magnification 100×. F: Median lobe of the liver of a Lewis rat given 3.0 μg/day of rotenone for 28 days. Simple severe thinning of hepatic cords due to hepatocellular atrophy, with loss of clear cytoplasm and lipid vacuoles, interpreted as loss of glycogen content, typical of rats with anorexia. HE. Original magnification 100×.
The results of alpha-synuclein immunostaining of the SNc indicated that there were alpha-synuclein positive cells in a few of the rotenone-treated rats (Figs. 4 and 5).

The alpha-synuclein staining was variable among rats while there were more positive cells in some of the rotenone-treated rats, without an increase alpha-synuclein staining in several others.

### 3.4. Peripheral organ pathology

#### 3.4.1. Subcutaneous model

Four rats (20%) died spontaneously after 3–5 days of rotenone administration (3.0 mg/kg/day). No peripheral organ pathology was performed on these rats. These mortalities were attributed to treatment. In the surviving rats, treatment-related and significant changes were observed in the stomach and minor changes were observed in the liver and heart which were considered to be related to rotenone administration and are summarised in Table 5. Some minor changes were also seen in the liver and adrenals, which were most probably the consequence of decreased food consumption or complete anorexia and stress, respectively.

Time-related increase in incidence and severity of gastric mineralisation, confirmed by a Von Kossa stain, was observed in the smooth muscles fibers, the elastic connective tissue and occasionally in the glandular epithelial cells of the muscular layer, the submucosa, the muscularis mucosa and glandular crypts of the stomach (Fig. 6A and B). In the heart, minimal myofiber necrosis characterised by significant coagulative necrosis of myofibers and an inflammatory response was observed in two rotenone-treated rats sacrificed on day 14 (Fig. 6C). In the liver, slight increase in centrilobular single cell necrosis and/or inflammation was noted in 2 rats sacrificed on day 14, above what is usually seen in overnight fasted albino rat controls (Fig. 6D). A decrease in glycogen content was found in a majority of rats (Table 5), which was characterised by a marked decrease or an absence of clear cytoplasmic spaces without sharp outlines, a smaller size of hepatocellular trabeculae and was accompanied by centrilobular hepatocellular atrophy in
Table 6

To determine transport of fluorescein across the BBB, the AUCECF/AUCplasma ratio was calculated. The data are presented as mean values±SEM.

4. Discussion

In this study we compared the subcutaneous and intracerebral administration of rotenone to develop a rat model for Parkinson’s disease. We examined brain histology, peripheral toxicity, behaviour and BBB permeability.

4.1. Subcutaneous model

The subcutaneous infusion of rotenone resulted in minor development of dopaminergic lesions whereas profound peripheral organ toxicity was found. Although the subcutaneous infusion seemed to affect locomotor behaviour and seemed to induce an increase in BBB permeability compared to the control infusion (saline and vehicle), these results could not be correlated to nigrostriatal injury, but were most probably a consequence of peripheral organ toxicity. A time-related increase in incidence and severity of mineralisation (calcification) in the stomach was observed in rotenone-treated rats and is clearly related to the systemic rotenone administration. Since there were no significant kidney lesions, the mineralisation is probably dystrophic secondary to cellular injury/necrosis, instead of metastatic associated with hypercalcemia or systemic Ca/P imbalance related to renal failure (uremia) (Cotran, Kumar, & Collins, 1999; Palmer, 1993). However, this change would deserve further investigations to definitively rule out a metastatic mechanism. The mineralisation (calcification) in the stomach of rotenone-treated rats could be the consequence of mitochondrial injury due to inhibition of complex I and/or oxidative stress and secondary calcium influx (Sousa, Maciel, Vercesi, & Castilho, 2003; Sousa & Castilho, 2005). The reason as to why the damage is localised to the stomach remains unsolved. A reduced blood-flow to the stomach as a result of chronic excessive stomach distension could be an explanation, although mucosal thinning which is indicative of excessive distension was not consistently observed. This change has not been, to our knowledge, previously reported in rats that received rotenone systemically. Stomach distension is usually a non-specific change related to physiological demise, nausea (pica), severe stress or exaggerated pharmacological effect and there were no morphological evidences of atrophy of parietal cells, which could support the previously published hypothesis of achloridria with decreased wall mass (Lapointe et al., 2004). The observed cardiac changes in 2 rotenone-treated rats were attributed to treatment, since none were observed in any of the saline- or vehicle-treated rats and this change is not common in albino rats of that age; however, a background change cannot strictly be ruled out, since this change may occasionally be found in control Fischer 344 or Sprague Dawley rats (Boorman, Eustis, Elwell, Montgomery, & Mackenzie, 1990). Liver changes were minor
and related to decreased bodyweight with time and suspected decrease in food consumption. All of these changes could be secondary to the gastric lesions, especially the observed decrease in glycogen content. In addition, a few animals had atrophy of hepatocellular cords along with increased single cell necrosis, inflammation and hepatocellular microvacuolation. Although these changes could be associated with starvation, a rotenone-related effect cannot be ruled out. In contrast to a previous report with similar experimental conditions, hepatocellular coagulative necrosis was not reported in this study (Lapointe et al., 2004).

The peripheral toxicity, high mortality and variability in the development of dopaminergic lesions in the brain of systemically administered rotenone as we have seen in our experiments are confirmed by literature (Betarbet et al., 2000; Fleming et al., 2004; Hoglinger et al., 2003; Lapointe et al., 2004; Sherer et al., 2003; Zhu et al., 2004) although it has not been so extensively investigated as in the experiments described in this paper. In conclusion, these results indicate that the subcutaneous infusion of rotenone in the rat causes significant systemic toxicity, notably important and adverse changes in the stomach and heart, while not able to produce a sufficient amount of nigrostriatal damage as referred to as golden standard for Parkinson’s disease.

4.2. Intracerebral model

The intracerebral infusion caused a progressive, dose-dependent decrease in dopaminergic neurons to about 30% in 28 days, with a few cases alpha-synuclein immunoreactivity and aggregation but without any peripheral toxicity or any effect on bodyweight. Although the alpha-synuclein inclusions were not directly related to the severity of the dopamine lesions, they have not been observed in previous experiments using an intracerebral infusion of rotenone (Alam et al., 2004; Antkiewicz-Michaluk et al., 2004; Saravanan et al., 2005; Sindhu et al., 2005) and this result is therefore one step closer to mimicking the human pathology of Parkinson’s disease. Saravann et al. observed a dose-dependent (2, 6 and 12 μg) decrease in striatal biogenic levels already on day 5 after the infusion (Saravanan et al., 2005). In our studies, we used a lower concentration range which may account for the fact that we do not see a clear dose-dependent decrease in the first 4 to 7 days. Furthermore, the decrease TH staining in time is most evident at 5.0 μg, specifically in the SNC. In the striatum the decrease seems to reach a minimal plateau after 28 days. Moreover, there appears to be an increase in TH staining in both the striatum and SNC for the 2.0 μg dose between day 14 and 28. This could perhaps be explained by the relatively low concentration infused, some rats being less susceptible to rotenone and general variability with this toxin. Variability has also been observed in response to systemically treated rotenone rats (Betarbet et al., 2000; Sherer et al., 2003). It would be of interest to look at higher doses and for a longer period of time and perhaps compare different strains of rats specifically for the infusion of rotenone into the MFB. The amphetamine induced rotational behaviour of the intracerebral infused rotenone rats (5.0 μg) showed a significant preference of these rats for rotating in the ipsiversive direction on day 21 which was consistent with a unilateral lesion in the brain dopaminergic system. These results were somewhat different from a study by Sindhu et al. (2005) where they did not see any significant stereotypic rotations in MFB-lesioned rats (12 μg) until day 28. Again these differences may be due to variation among rat strains (Lewis rats compared to Sprague Dawley rats).

In contrast to what would be expected from literature (Alexander, Schwartzman, Grothusen, & Gordon, 1994a; Carvey et al., 2005; Kortekaas et al., 2005), the microdialysis data showed no significant difference between the rotenone and sham infused rats, indicating no difference in BBB permeability in the striatum in the Parkinson’s diseased brain. However, as the microdialysis study was performed at one particular timepoint at a specific location in the brain, it cannot be concluded that no changes in BBB permeability would occur in other stages of the disease, or at other places within the brain. While microdialysis is a good technique to study BBB transport characteristics as it monitors concentrations in the ECF in time (de Lange, Danhof, de Boer, & Breimer, 1997; Hammarlund-Udenaes, Paalzow, & de Lange, 1997), it does not provide spatial information from a specific location in the brain. In our view further investigations on BBB transport mechanisms are needed, to be performed in a strict mechanistic and quantitative manner, as a function of the disease state.

The intracerebral administration of rotenone creates the opportunity to develop an animal model for Parkinson’s disease, in which the toxin is delivered in its target organ-reducing side-effects in other parts of the body that may interfere in the investigations — with features getting closer to those in Parkinson’s disease patients. However, upon local delivery of the toxin, the question remains to be answered on how toxins which are capable of inducing Parkinson’s disease in human are able to reach their target in the brain. Further experiments to follow the progression at longer timepoints would be required to evaluate if indeed there is further disease progression and further alpha-synuclein development beyond 28 days. Since age seems to increase the sensitivity of dopaminergic neurons to rotenone toxicity (Phinney et al., 2006), it would be worthwhile to investigate this for the IC infused rotenone rats and the influence that age might have on the development of alpha-synuclein inclusions.

Comparing these results to the more commonly used 6-OH-DA model, in our hands, 6-OH-DA infusion into the nigral cell bodies (O’Neill et al., 2004) or into the MFB (Visanji et al., 2006) produces a more rapid (5–10 days) loss in terminals. Also, when infused into the SNC, 6-OH-DA causes an anterograde degeneration of the whole nigrostriatal dopaminergic system (O’Neill et al., 2004; Sachs & Jonsson, 1975), resulting in a more rapid loss of tyrosine hydroxylase positive cells. Thus, the seemingly slower effects of MFB infused rotenone obtained thus far favours a more chronic model than 6-OHDA and this might be due to differences in the solubility, stability, diffusion of the toxin or the mechanism by which the toxin produces cell death. 6-OH-DA can be infused into the striatum and while a rapid loss in terminals is observed this model also produces slow progressive retrograde damage to the nigral cells (Murray et al., 2003; Rosenblad et al., 1999), but no alpha-synuclein inclusions have been observed so far in this model. Taken as a whole the data presented here indicate that rotenone infused intracerebrally is able to create a progressive rat model for Parkinson’s disease, which could then be used in PD and other types of experiments.
Acknowledgement

The authors would like to acknowledge Dr Daniel G. Rudmann for critically reviewing the pathology section of the manuscript and the outstanding technical assistance of Claudine de Boelpaep in preparing the tissues for pathological assessment. The described work was financially supported by Lilly Development Centre, Mont-Saint-Guibert, Belgium.
