 Conjunctive input processing drives feature selectivity in hippocampal CA1 neurons

Katie C Bittner1, Christine Grienberger1, Sachin P Vaidya1, Aaron D Milstein1, John J Macklin1, Junghyup Suh2,3, Susumu Tonegawa2,3 & Jeffrey C Magee1

Feature-selective firing allows networks to produce representations of the external and internal environments. Despite its importance, the mechanisms generating neuronal feature selectivity are incompletely understood. In many cortical microcircuits the integration of two functionally distinct inputs occurs nonlinearly through generation of active dendritic signals that drive burst firing and robust plasticity. To examine the role of this processing in feature selectivity, we recorded CA1 pyramidal neuron membrane potential and local field potential in mice running on a linear treadmill. We found that dendritic plateau potentials were produced by an interaction between properly timed input from entorhinal cortex and hippocampal CA3. These conjunctive signals positively modulated the firing of previously established place fields and rapidly induced new place field formation to produce feature selectivity in CA1 that is a function of both entorhinal cortex and CA3 input. Such selectivity could allow mixed network level representations that support context-dependent spatial maps.

The neuronal microcircuit is a fundamental processing unit of nervous systems and as such is intricately involved in producing the network computations that drive behavior. Many cortical microcircuits show a stereotyped organization that may allow them to implement a common set of core operations1. One such core operation is derived from the fact that most cortical microcircuits receive at least two functionally distinct afferent inputs from different brain areas2. In pyramidal neuron–based microcircuits, these different inputs are spatially segregated, with long-range inputs mainly innervating the most distal apical tuft dendrite regions and more local inputs usually forming synapses onto the proximal perisomatic dendrites2–5. The electrical isolation present in most pyramidal neurons means that each functional class of inputs is initially processed in relative independence of the other6–9. However, active dendritic mechanisms, such as backpropagating action potentials (APs) and dendritic Ca2+ plateau potentials, allow the different afferent input streams to interact nonlinearly when they arrive with appropriate coincident timing6–13. Additionally, the initiation of dendritic plateau potentials is known to robustly induce rapid and long-lasting changes in synaptic strength and dendritic excitability10,14. This form of input interaction or integration could support a nonlinear combination of the input streams to produce neurons with a feature selectivity that is a function of both input paths6,9. Such a population will, in turn, generate mixed or multimodal network representations with advantageous computational properties15,16.

In the CA1 region of the hippocampus, long-range external information from entorhinal cortex (EC3) arrives onto the most distal dendritic regions of principal neurons while more local, internal information from hippocampal area CA3 arrives onto proximal perisomatic dendrites2,3,17,18. In vitro studies have shown that these inputs can be integrated supralinearly, with the exact level of amplification being dependent on the coincidence of the two input pathways. A voltage-gated Ca2+ channel and NMDA receptor-dependent dendritic plateau potential generated in the distal apical dendritic regions mediates this nonlinear form of dendritic integration9–11. Recently, several in vivo studies have provided strong evidence that dendritic plateau potentials and the complex burst firing they produce are present during both anesthetized and awake conditions13,19–21. Such active dendritic processing could mediate a nonlinear interaction between EC3 and CA3 inputs that allows the CA1 circuit to associate contextual and spatial information, thus generating and maintaining context-dependent spatial maps10,22–25.

RESULTS

Intracellular characterization of place-specific firing

To investigate dendritic plateau potentials in awake, behaving mice, we trained water-restricted mice to run head-fixed on a linear track treadmill with spatial cues for a 10% sucrose water reward delivered each trial (lap) at the same location on a ~2 m track (Fig. 1a; see Online Methods)26. Extracellular recordings under these conditions have demonstrated that CA1 pyramidal neurons fire at specific locations on the track and that these place cells have similar properties to those recorded from freely moving animals26. We obtained simultaneous whole-cell intracellular and local field potential (LFP) extracellular recordings in area CA1 of the dorsal hippocampus of navigating mice (Fig. 1b). The activity profiles of recorded neurons generally fell into three categories: silent cells, non-place cells and place cells (Supplementary Fig. 1; see Online Methods for criteria).

we will restrict our analysis to place cells, which exhibited location-specific AP firing at rates that were similar to those measured using extracellular methods (mean peak rate, 14.3 ± 1.5 Hz, N = 22 neurons from 21 mice; Fig. 1 and Supplementary Fig. 2)\textsuperscript{26}. In accord with previous intracellular recordings of place cells\textsuperscript{19,20}, we observed a ramp-like depolarization in the subthreshold membrane potential (ramp) (mean ramp amplitude, 7.9 ± 1.0 mV, N = 22; Fig. 1 and Supplementary Fig. 2), an increase in the amplitude of intracellular theta oscillation (theta\textsubscript{a}) (mean Δtheta, 2.8 ± 0.26 mV, N = 22; Fig. 1 and Supplementary Fig. 2) and phase precession of both APs and theta\textsubscript{a} at the preferred firing location (Supplementary Fig. 2). The entire population of place fields spanned the length of the belt (Fig. 1d).

**Detection and properties of dendritic plateau–driven complex spiking and burst firing**

We also observed bursts of APs that were driven by characteristic membrane potential (V\textsubscript{m}) depolarizations that are the signature of dendritic plateau potential initiation (Fig. 1e–g and Supplementary Fig. 3)\textsuperscript{10,11,19,20}. Plateau events were detected as a threshold crossing (−35 mV) of the smoothed intracellular voltage (Supplementary Fig. 3). The threshold value was determined from dual dendritic and somatic in vitro voltage recordings with simultaneous calcium imaging (Supplementary Fig. 3f–j). The average duration of plateau events in vivo, measured as the time spent above threshold, was 56 ± 4 ms and the amplitude of these events from baseline V\textsubscript{m} was 41 ± 0.3 mV (Fig. 1h,i, N = 17 cells, 226 events), similar to that recorded in vitro (Supplementary Fig. 3) and from anesthetized mice\textsuperscript{21}. We also found that the probability of plateau initiation varied between laps and was positively correlated with ramp amplitude, Δtheta and peak firing rate (Supplementary Fig. 4). NMDA receptor blockade using intracellular MK801 reduced plateau probability and duration, which is consistent with the pharmacology of plateau potentials recorded in vitro and in anesthetized mice (Supplementary Fig. 5)\textsuperscript{10,11,21}.

**Spatio-temporal properties of plateaus**

To examine the microcircuit mechanisms of plateau potential initiation, we measured the extracellular theta phase preference of plateaus and APs in all place cells. In vitro studies predict that plateaus should be initiated when EC3 and CA3 input are coincidently active. Extracellular studies, however, have shown that EC3 and CA3 inputs tend to be active at different phases of theta, with the phase preference of EC3 being near the peak of theta while CA3 inputs are most active near the trough of extracellular theta\textsuperscript{27,28}. Consistent with previous reports for CA1 cells, the phase preference of APs recorded here was near the trough of extracellular theta (173 ± 16°; 12,784 events in 21 neurons). The phase preference of plateaus, however, was more advanced than that of APs (56 ± 7°; 223 events in 16 neurons; two-tailed unpaired t-test, P = 1.8 × 10\textsuperscript{−6}; Fig. 2b), making their phase preference more similar to that previously reported for EC3 input. Plateaus also displayed a significantly higher level of theta modulation (APs, 0.43 ± 0.04; plateaus, 0.92 ± 0.03; two-tailed unpaired t-test, P = 4.9 × 10\textsuperscript{−4}). Interestingly, we observed a relationship between

plateau probability and AP theta phase preference of individual neurons: plateau probability was higher in those cells showing the most advanced theta phase preference (Fig. 2c). Plateau durations also had a phasic relationship with the LFP, such that the duration of plateau events decreased as the theta phase of their initiation moved from the peak of extracellular theta to the trough, farther from the preferred phase of EC3 input (Fig. 2d). Together these results are consistent with previous in vitro data showing that dendritic Ca\(^{2+}\) plateaus occur when CA3 input is appropriately timed to drive AP output and back-propagation to coincide with EC3 input.

Experimental manipulation of perisomatic V_m and AP firing phase

We further examined this temporal relationship by manipulating the phase of perisomatic V_m fluctuations and resultant CA1 firing, thereby mimicking the impact of either advanced or delayed CA3 input. For this we used a closed loop experiment in which we online filtered and variably delayed the extracellular LFP and then used the resulting waveform to drive current injection into the recorded cell (Fig. 2 and Supplementary Fig. 6). In the first condition we minimized the delay to produce advanced V_m fluctuations and spiking biased toward the peak of extracellular theta (AP peak near 45°; Fig. 2e,g). In the second condition we increased the delay on the injected current to produce later phase V_m fluctuations, and the cells preferentially spiked near the trough of extracellular theta (∼200°; ∼95 ms delay; Fig. 2f,g). Plateau probability and normalized duration were significantly higher when spiking was biased toward the peak of extracellular theta (probability, 4.1 ± 1.2 plateaus per 100 APs; duration 183.2 ± 41 ms per 100 APs; N = 6; Fig. 2i,j) than when spiking was near the trough (probability, 1.3 ± 0.4 plateaus per 100 APs; duration 63.5 ± 33.5 ms per 100 APs; N = 6; Fig. 2i,j) even though the average firing rates were similar under the two conditions (peak, 8.6 ± 1.4 Hz; trough, 7.8 ± 1.7 Hz; N = 6). The phase preference of plateaus under these conditions was similar to that of the control (Fig. 2h). This manipulation provides further evidence that plateau potentials in CA1 pyramidal neurons are preferentially generated when CA3 input drives AP output to coarsely overlap with synaptic input from EC3.

Experimental reduction of EC3 input to CA1

To elucidate the role of the distal long-range input, we recorded from mice expressing archeaerhodopsin (Arch) in EC3 pyramidal cells (see Online Methods and Fig. 3a). We inhibited synaptic input from EC3 neurons by activating Arch in the axons and terminals of these cells using an optical fiber fitted inside the LFP electrode that was located in the stratum radiatum near the recorded neuron (3–5 s duration 594-nm laser pulses; Supplementary Fig. 7). A similar manipulation reduced the time integral of synaptically evoked postsynaptic potential (EPSP) (as measured by area under the curve) ∼30% in hippocampal brain slices from these transgenic mice (Supplementary Fig. 8). Activation of Arch influenced our measures of burst firing (Fig. 3b,e,f) and significantly reduced plateau probability and normalized duration by ∼50% (no light versus light: probability, 3.8 ± 0.8 versus 1.7 ± 0.5 plateaus per 100 APs; duration, 63.4 ± 6.8 versus 27.8 ± 6.0 ms per 100 APs; N = 8 neurons; Supplementary Fig. 9c–e) whereas running speed was comparable for laps with and without light stimuli (no light, 29.6 ± 1.6 cm/s; light, 28.5 ± 1.3 cm/s; N = 8). This manipulation of the distal synaptic input stream indicates that EC3 input is critical in generating plateau potentials in awake, behaving mice.

EC3 and CA3 pathways in the generation of plateaus

We next examined the relative contribution of each individual pathway in plateau initiation by performing an in vitro experiment...
that allows independent pathway activation. Here we paired separate stimulation of either the EC3 or CA3 input pathways with long duration current injections (300–600 pA, 400 ms) into CA1 pyramidal somata (Fig. 3). Pairing of current injection with EC3 input pathway stimulation increased the occurrence of dendritic plateau potentials, quantified as the associated tuft Ca²⁺ signal area (measured as time integral of the change in fluorescence signal over baseline fluorescence, ∆F/F) (600 pA alone, 50 ± 11 ∆F/F ms; plus EC3, 151 ± 16 ∆F/F ms; N = 6 neurons; Fig. 3). This was not the case, however, when the same currents were injected together with similarly sized CA3 input pathway stimulation. Instead, Ca²⁺ plateau initiation was rare and the tuft Ca²⁺ signal was not different from that observed for current injection alone (600 pA alone, 50 ± 11 ∆F/F ms; plus CA3, 60 ± 10 ∆F/F ms; N = 6; Fig. 3). This result highlights the special, perhaps necessary, role of the EC3 pathway in the production of plateau potentials in CA1 pyramidal neurons. For its part, CA3 input appears to provide apical dendritic depolarization and, perhaps most importantly, to produce AP output that backpropagates into the distant regions of the apical dendrite to interact with the EC3 input.

Gain modulation of place-field firing by plateau initiation
To determine the impact of these events on CA1 output, we calculated plateau probability as a function of the animal’s location. We found when examining place field traversals that plateau probability was highest within the field and peaked near the place field center, consistent with previous reports of intracellulary recorded complex spiking (bootstraped permutation test, P ≈ 1 × 10⁻⁴; Fig. 4a–c). Notably, plateau potentials positively modulated the frequency of in-field AP firing (~30% increase in peak firing rate) in a manner consistent with an increase in firing rate gain and heavily increased the incidence of high-frequency firing and short inter-spike interval (ISI) events (Fig. 4d–f). These data indicate that the generation of plateau potentials elevates in-field AP firing frequency by promoting...

Spontaneous plateaus are associated with new place field formation

In addition to the above described ability of plateau potentials to produce a robust gain modulation of CA1 output, plateaus were also observed to be associated with the rapid formation of new place fields. A subset of pyramidal neurons abruptly transitioned from either silent or non-place firing into position-specific firing at a particular time during the recording session \((N = 6 \, \text{neurons}; \text{Fig. 5 and Supplementary Fig. 10})\). Inspection of the \( V_m \) traces during this transition revealed the presence of long-duration, plateau-driven complex spiking that consisted of bursts of high-frequency APs riding on top of large \((-40 \, \text{mV})\) and long-lasting \((138 \pm 23\, \text{ms})\).

N = 22 events) depolarizations in all neurons that formed new place fields (Fig. 5a-c and Supplementary Fig. 10). $V_m$ traces from laps following the dendritic plateau potential displayed a consistent location-specific increase in firing rate (mean peak firing rate 12.7 ± 2.2 Hz; N = 6) that was driven by large-amplitude, slow $V_m$ depolarizations (ramp; before, 0.8 ± 0.2 mV; after, 6.9 ± 1.0 mV; N = 6; $P = 2.3 \times 10^{-9}$, paired two-tailed t-tests) and substantial intracellular $V_m$ theta oscillations ($\Delta$theta; before, 0.6 ± 0.2; after, 1.7 ± 0.4 mV; N = 6; $P = 1.6 \times 10^{-4}$, paired two-tailed t-tests) at the location on the track where the plateau had appeared for the remaining duration of the recordings (19.8 ± 4.2 laps; 9.6 ± 1.2 min; N = 6) (Fig. 5 and Supplementary Fig. 10). The above data suggest a role for dendritic plateau potentials in the rapid formation of new place fields in CA1 pyramidal neurons.

Induced plateaus drive new place field formation

To more directly test whether plateau potentials are sufficient to induce place field formation, we developed a closed-loop experiment to evoke plateau potentials at specific locations along the track. Although naturally occurring plateaus require coincident input from CA3 and EC3, we were able to induce plateau potential initiation through intracellular current injection (300 ms, \~600 pA, Fig. 6) at the same location along the track for repeated laps (~5 laps; Fig. 6 and Supplementary Fig. 11). The induced plateau potentials had similar properties to naturally occurring plateaus (phase preference, $25^\circ \pm 15^\circ$; $N = 102$ events; phase modulation index, $0.83 \pm 0.04$; $N = 102$ events; duration, $56 \pm 10$ ms, $N = 141$ events). Such repeated plateau initiation was sufficient to induce spatially selective AP firing at the location of the current injection (mean peak firing rate $15.4 \pm 2.1$ Hz; $N = 14$ neurons) in 93% of cells tested (14 of 15 neurons). This position-specific firing was driven by the rapid appearance of a large-amplitude $V_m$ depolarization (ramp; before, $0.8 \pm 0.2$ mV; after, $7.2 \pm 0.6$ mV; $N = 14$; $P = 2.3 \times 10^{-11}$, paired two-tailed $t$-tests, Fig. 6d,e,g) and $V_m$ theta oscillation ($\Delta$theta; before, $0.6 \pm 0.2$ mV; after, $1.7 \pm 0.2$ mV; $N = 14$; $P = 7.4 \times 10^{-8}$, paired two-tailed $t$-tests; Fig. 6d,e,h). The induced place fields were stable for the remaining duration of the recording ($15.1 \pm 1.8$ min; $N = 14$) and for many laps ($39 \pm 7$; $N = 14$). In most respects, the induced place fields were similar to those of non-induced place cells: the mean peak firing rate, ramp amplitude, phase precession of APs, phase precession of intracellular theta and AP theta phase preference were not significantly different from those of standard place cells (Supplementary Fig. 11d–f; two-tailed unpaired $t$-tests, $P = 0.22, 0.46, 0.067, 0.09$ and 0.28, respectively). However, $\Delta$theta was slightly, but significantly, lower in the induced place fields when compared to standard place cells (Supplementary Fig. 11e; two-tailed unpaired $t$-test, $P = 0.001$).

Input resistance did not change following place field induction (before, $69.5 \pm 2.8$ M$\Omega$; after, $73.1 \pm 3.5$ M$\Omega$; $N = 14$ neurons, $P = 0.48$; paired two-tailed $t$-test; Supplementary Fig. 12). The amplitude of the resulting position-specific increase in $V_m$ ramp depolarization and firing rate also did not vary as a function of position for induced plateau initiation ($N = 14$; $F = 0.2425$, ANOVA; Fig. 6k). This indicates that there was no spatial bias to place-field generation and that the only determinant was the position of repeated plateau potential initiation. These observations suggest that CA1 pyramidal neurons receive proportional amounts of input from presynaptic cells that are tuned to all possible spatial locations and as a result are equally capable of expressing place-specific firing at any potential position.

High-frequency single spiking is not effective

To determine whether the plateau potentials or the associated high-frequency AP firing was the main driver of place field formation, we next used a current-injection waveform that generated a similar number of high-frequency AP trains but that did not contain any plateau potentials (train of 30 APs at 100 Hz, \~1-nA, 2-ms-duration pulses). The trains of APs induced only a small increase in the ramp amplitude (ramp; before, $1.1 \pm 0.3$ mV; after, $1.9 \pm 0.4$ mV; $N = 6$
neurons; \( P = 0.007 \), paired two-tailed \( t \)-tests) that was both smaller than that induced by plateau initiation \((P = 4.7 \times 10^{-5}; \text{unpaired two-tailed} \ t\)-test) and insufficient to produce a lasting increase in position-specific firing rate \((0.8 \pm 0.1 \text{ Hz}; \text{N} = 6; \text{Supplementary Fig. 13})\). There was no significant effect on intracellular theta oscillations \((\Delta \text{V}_m)\) and the locations of the ripple relative to the place field center \((\text{at} \ 0)\) before \((\text{black open circles})\) and after \((\text{gray filled circles})\) place field formation. Data are taken from the cell shown in \( \text{a} \). Each circle represents one ripple \((\text{before}, \text{N} = 230 \text{ ripples}; \text{after}, \text{N} = 340 \text{ ripples})\); the lines show linear fits. Ripple locations before and after the place field center were pooled. \( \text{b} \) Number of APs per ripple for events inside and outside the neuron's place field \((\text{mean} \pm \text{s.e.m.}, \text{N} = 16 \text{ neurons}, \text{two-tailed unpaired} \ t\)-test, before versus after \( P = 4.0 \times 10^{-4}, \text{after inside versus after outside} \ P = 0.017)\). \( \text{c} \) \( \Delta \text{V}_m \) for ripples inside and outside the neuron's place field \((\text{mean} \pm \text{s.e.m.}, \text{N} = 16 \text{ neurons}, \text{unpaired two-tailed} \ t\)-test, before versus after \( P = 1.0 \times 10^{-4})\).

Plateaus increase the amplitude of incoming input

We next sought to determine the mechanism of the plateau-induced formation of new place fields. Given the previously described ability of plateau potentials to induce synaptic plasticity, it is a straightforward prediction that synaptic potentiation at the position of the plateaus drives subsequent place-specific firing. Alternatively, plateaus could produce an increase in the frequency of inputs present at a given position of the track. An analysis of \( \text{V}_m \) fluctuations can distinguish between these two possibilities, as \( \text{V}_m \) variance is a linear function of the frequency of inputs but increases as the square of EPSP amplitude \((\text{Supplementary Fig. 14})\). The analysis showed that both spontaneous and induced place field generation caused the variance of \( \text{V}_m \) fluctuations within the fields to increase nearly fourfold over that of laps without place field firing \((\text{before}, 2.4 \pm 0.1 \text{ mV}^2; \text{after}, 8.0 \pm 0.8 \text{ mV}^2; \text{N} = 19 \text{ neurons}; \text{P} = 8.5 \times 10^{-9}; \text{paired two-tailed} \ t\)-tests; \text{Fig. 7})\), and variance was found to increase as approximately the square of the mean \( \text{V}_m \) \((\text{variance versus mean plots were best fit by a power function with mean power} = 1.7 \pm 0.2; \text{N} = 19 \text{ neurons})\). Additionally, place field generation caused an increase in the higher order moments \((\text{particularly excess kurtosis})\) of the \( \text{V}_m \) distribution \((\text{before}, 0.36 \pm 0.08; \text{after}, 1.0 \pm 0.2; \text{N} = 19 \text{ neurons}; \text{P} = 3.2 \times 10^{-5}; \text{paired two-tailed} \ t\)-tests; \text{Fig. 7f,h})\). The observed large increase in \( \text{V}_m \) variance within the induced place fields and the supralinear relationship to the mean \( \text{V}_m \) is consistent with a position-specific increase in EPSP amplitude rather than an increase in the frequency of the synaptic inputs \((\text{Supplementary Fig. 14})\).

We next performed the \( \text{V}_m \) fluctuation analysis on place cell and silent cell populations. This analysis showed that place cells had within-field \( \text{V}_m \) variance that was approximately four times that of silent cells \((\text{silent cell}, 2.0 \pm 0.2 \text{ mV}^2, \text{n} = 10; \text{place cell}, 8.8 \pm 1.4 \text{ mV}^2, \text{n} = 12; \text{P} = 4.8 \times 10^{-7}; \text{unpaired two-tailed} \ t\)-tests; \text{Fig. 7g})\) and was not different from that in neurons with induced place fields \((\text{unpaired two-tailed} \ t\)-test, \text{P} = 0.42; \text{Fig. 7g})\). The degree of nonlinearity in the relationship between \( \text{V}_m \) variance and mean was also not different from that of induced place fields \((\text{power} = 1.6 \pm 0.2; \text{N} = 15 \text{ neurons}; \text{unpaired two-tailed} \ t\)-test, \text{P} = 0.30)\). Together these analyses support the idea that an elevation in position-specific synaptic weight is an important mechanism underlying place-field firing in hippocampal CA1 pyramidal neurons.

Impact on sharp wave/ripple–related activity

Finally, we observed that the induction of new place fields by plateau potential initiation during active running was associated with an alteration in the activity of neurons during subsequent sharp wave/ripple \((\text{SPW/R})\) network states that occurred within nonexploratory periods. When rodents stop actively exploring an environment, the hippocampus transiently enters a distinct network state that is characterized by short-duration \((<100 \text{ ms})\), high-frequency \((-200 \text{ Hz})\) oscillations in the extracellular field potential \((\text{Fig. 8})\). Intracellular \( \text{V}_m \) depolarization produced during ripple activity was significantly enhanced following the induction of place fields during active exploration \((\text{before}, 2.0 \pm 0.3 \text{ mV}; \text{after}, 4.3 \pm 0.2 \text{ mV}; \text{N} = 16; \text{Fig. 8c})\).
Furthermore, this enhanced $V_m$ depolarization also increased the number of APs produced during ripple activity (before, 0.01 ± 0.004 APs; after, 0.10 ± 0.025 APs; $N = 16$; Fig. 8d). The effect, particularly on AP firing, was most pronounced when ripples occurred at positions on the track that were near the location of the induced place field (after inside place field, 0.154 ± 0.034 AP; after outside place field, 0.047 ± 0.026 AP; $N = 16$; Fig. 8d). These data indicate that a common mechanism, plateau potential–mediated plasticity, underlies neuronal feature selectivity during both distinct hippocampal network states (theta versus SPW/R states), further strengthening the idea that the neuronal activity associated with ripples is a reactivation of the activity that occurred during active exploration.

**DISCUSSION**

We show that dendritic plateau potentials enhance place field firing rates and the incidence of complex spike burst firing in CA1 pyramidal neurons. The timing of plateau potential initiation coincides with EC3 input to CA1 cells, and plateau probability is increased when perisomatic $V_m$ is manipulated to drive CA1 spiking near the theta phase preference of EC3 input. Furthermore, optogenetic inhibition of EC3 input in the behaving animal, as well as independent pathway activation in the slice, suggest a unique role for EC3 input in the generation of dendritic plateau potentials. These data are consistent with previous *in vitro* studies showing that dendritic plateau potentials produce a nonlinear integration of CA3 and EC3 input streams, the size of which is related to the degree of correlation.

In addition, the data show that dendritic plateau potentials are sufficient to induce place field formation in CA1 pyramidal cells and that the underlying mechanism is likely to be a strengthening of synaptic inputs active around the time of plateau generation. The ability of plateaus to induce fields at any position along the track indicates that a given CA1 pyramidal cell receives input tuned to all spatial locations and is therefore equally able to express location-specific firing at any position. We did not find any evidence of a position-specific bias in the number or frequency of inputs, suggesting that CA1 cells receive an approximately proportional amount of inputs for all regions of the linear track and that the generation of a long-duration plateau potential chooses the particular feature for which the neuron will be selective (Supplementary Fig. 15). The plateau potential–driven increase in synaptic input also appears to result in an enhanced reactivation during SPW/R activity, implicating a common mechanism for position-specific firing during both active exploration and non-exploratory network states. Furthermore, since CA3 is considered to be the source of SPW/R activity *in vitro* and *in vivo*, the plasticity evoked by dendritic plateaus should involve CA3 inputs to CA1 pyramidal neurons.

The two mechanisms currently thought to be involved in the formation of place fields in hippocampal neurons are a linear combination of different periodic grid cell inputs and various Hebbian synaptic plasticity mechanisms. The data presented here indicate that input-potentiating plasticity mechanisms rather than location-dependent increases in input numbers are the most prominent determinant of position-selective firing in CA1 place cells. However, there remains the possibility that variations in EC3 input, mediated by overlapping grid-cell input, may regulate the probability of plateau potential initiation in a position-dependent manner. This could potentially connect the two mechanisms. The observation that dendritic plateau potentials were much more effective than high-frequency APs at rapidly producing long-lasting place-specific input potentiation has implications for the rules governing place field formation in CA1 pyramidal neurons. Since plateau potentials are induced by the conjunction of two input pathways (EC3 and CA3), it follows that CA1 neurons may use nonstandard associative learning rules to form place fields with properties that are a function of both CA3 and EC3 input. More experiments are needed to determine the exact synaptic mechanisms and induction rules involved in the generation of CA1 place fields.

The spontaneous plateaus that were found to induce place fields were approximately three times as long as those plateaus produced within existing place fields or those induced by current injections. This suggests that there may be some special condition associated with their initiation. Such a condition could be subcortical input driving both the dendritic disinhibition and neuromodulation that are likely required for such long-duration events. Future experiments manipulating these elements should reveal the detailed circuit mechanisms involved in spontaneous plateau generation. In the end, the plasticity produced by plateau potentials is capable of generating a place field in a single trial, and such rapid field induction is a known property of CA1 pyramidal neuron activity during exploration. While it is not entirely clear how long newly generated place fields will persist, the continued generation of plateau potentials within the new field could enhance their stability and this could be another important function for plateau generation within place fields.

Although we have above mainly focused on the role of excitatory input in dendritic plateau potential generation, inhibitory inputs are also likely to be important in regulating these signals. In particular, dendritically targeting interneurons that display a late theta phase firing preference are well suited to control the initiation and duration of dendritic plateau potentials. Along these lines, oriens-lacunosum-molecular (OLM) interneurons are known to reduce complex spike probability and duration as well as influence spatial learning, underscoring the role of inhibitory elements in this microcircuit operation.

This and other studies present evidence that active dendritic integration in pyramidal neuron based cortical microcircuits supports a fundamental operation, the nonlinear interaction of long-range and local inputs that leads to firing rate modulation and neuronal plasticity. Indeed, evidence of a similar nonlinear modulation of tuned responses by active dendritic processing has been reported in layer 5 pyramidal neurons of the barrel cortex of behaving mice, and a comparable form of dendritic plateau–driven plasticity has been observed in neocortical neurons both *in vitro* and in anesthetized mice. Additional experiments are needed to fully explore the roles of various cortical microcircuit elements in what appears to be a candidate general microcircuit operation or low-level computation.

ONLINE METHODS

Animal experimentation. All experiments were performed according to methods approved by the Janelia Farm Institutional Animal Care and Use Committee (protocol 12-84).

Surgery and training schedule. Custom-made titanium head plates with an opening over the right hippocampus were affixed to the skulls of 5- to 6-week-old mice using Locite brand cyanoacrylate glue and dental acrylic while under either isoflurane or ketamine/xylazine anesthesia. The skull underneath the head implant opening was covered with cyanoacrylate glue and future locations for the craniotomies for the whole cell and field recordings were marked using stereotactic coordinates (2.0 caudal, 1.7 lateral for whole cell and 3.6–3.7 caudal, 1.7 lateral for field). After 5–7 d of recovery from surgery, running wheels were added to the cages and animals were placed on a water schedule protocol receiving 1.5 ml/d. After 5–7 d of water scheduling, animals were placed on the head fixation apparatus on either a training rig or the experimental rig for 20- to 40-min sessions per day for 5–14 d. Mice were trained to run for a 10% sucrose/water reward delivered once for every rotation of the belt (approximately 2 m) at the same location through a licking port. Mice were supplemented with additional water after training sessions to ensure they received 1.5 ml/d. Mice were used for recording after the number of trials (laps) completed per day was similar for 2–3 d. Animals that started training on the training rig were trained for at least two sessions on the experimental rig. The belt the animal used for training was the same belt used during the experimental session. The day before recording, animals were anesthetized using either isoflurane or ketamine/xylazine and two small (approximately 0.5 mm in diameter) craniotomies, one for the patch electrode and one for the field electrode, were drilled at previously marked locations. The dura was left intact and craniotomies were covered with silicone elastomer (Kwik-cast, World Precision Instruments).

Behavioral set-up and control. The linear track treadmill contains a belt made from velvet fabric (McMaster Carr) coated with visual and tactile cues as previously described.29 There were three types of cues covering the length of the belt: glue spines, Velcro tabs and white spots. The belt is self-propelled and the mouse experiences all three sets of local cues per rotation of the belt. The sucrose/water reward was delivered through a custom-fabricated lick port controlled by a solenoid valve (Parker) between the glue spines and Velcro. Licks were detected as a beam break using a through-beam optical sensor (Panasonic). Photoelectric sensors were positioned at three locations on the belt between each cue type and used to determine the relative location of the animal along the belt and trigger the reward delivery, laser shutter and spatial current injections. The animal’s speed was measured using a rotary encoder attached to one of the wheel axles. The valve, sensors and encoder were controlled with a custom-built microprocessor (Arduino) behavioral box interfaced with a Matlab graphical user interface. A separate microprocessor (Arduino) interfaced with a Matlab graphical user interface was used to control the laser shutter and spatial current injections on the basis of the animal’s relative position on the belt.

In vivo electrophysiology. For each animal before whole cell patching, the depth of the pyramidal cell layer was detected using an extracellular recording. Extracellular electrodes were glass patch electrodes broken so that the resistance when filled with 0.9% NaCl was 1.5–3 MΩ. The extracellular electrode used to determine the pyramidal cell depth for whole-cell recording was mounted vertically on a micromanipulator (Narishige) on a 40–45° angle relative to the bregma, unless otherwise indicated, and advanced through the more caudal craniotomy. For most experiments, this extracellular electrode was advanced until detection of the pyramidal cell layer but not through it. For EC3 inactivation experiments, the fiber-containing electrode was advanced approximately 200–300 µm beyond the pyramidal cell layer to position the light near EC3 axons. To correct for any location differences in theta phase between the LFP electrode location and the location of whole cell patch recordings, we recorded the two LFP signals simultaneously. Long-taper whole-cell patch electrodes (7–12 MΩ) were filled with (in mM) 134 potassium gluconate, 6 KCl, 10 HEPES, 0.3 Mg-GTP, 4 Mg-ATP and 14 Tris-phosphocreatine. Whole-cell patch electrodes were advanced through the cortex with 6–8 psi of pressure to prevent the electrode tip from clogging. Upon entry into the hippocampus (approximately 100–200 µm from depth measured using the extracellular electrode), the pressure was reduced to 0.3–0.4 psi. Cells were identified by reproducible increases in electrode resistance. All recordings were made in current clamp using a Dagan BVC-700A amplifier and digitized at 20 kHz using an Instrutech ITC-18 with HEKA Patchmaster acquisition software. For the experiments in Figure 2, the LFP was filtered using a single-pole high-pass filter with 1-Hz cut-off frequency followed by a second-order Butterworth low-pass filter with a 12-Hz cutoff, delayed, and amplified using a custom-built FPGA device controlled by a Matlab graphical user interface. The filtering procedure produced an ~25 ms lag in the peak of the filtered response as compared with the unfiltered LFP. During whole-cell recording, the amount of amplification was adjusted until the current injection was sufficient to elicit spiking in either of the two delay conditions. To bias spiking toward the peak of extracellular theta, the filtered LFP was used with either 0 or 10 ms additional delay over that introduced by the instrument (25–35 ms total delay). To produce spiking on the trough of extracellular theta, the LFP was filtered and inverted before injection (producing the equivalent of ~95 ms total delay). The exact timing of the current injection relative to the LFP was subject to any theta phase offsets between the local LFP and that at the recording location. All data were grouped on the basis of the actual timing of the spiking relative to the LFP phase as measured during data analysis.

Optical fiber–containing LFP electrode preparation. To prepare an optical fiber–containing electrode, 9 µm core fiber (1550 BHP, Thorlabs) with one end connectorized was loaded through the perfusion port of an electrode holder, stripped, cleaved, and etched in hydrofluoric acid in two steps: 5 mm of fiber etched to 30 µm diameter, then the last 1 mm of fiber etched to 8–10 µm. The etched fiber was loaded into a quartz (1.0/0.7 mm or 1.2/0.9 mm OD/ID, Sutter Instruments) electrode with a tip size of 12–20 µm. The fiber positioning inside the pipette was adjusted until the fiber tip was recessed 100–500 µm from the pipette tip. These optical fiber–containing electrodes (LFP/fiber) were filled with saline the day of the experiment and used on subsequent days until the power out of the device dropped by more than 30% or the electrical resistance doubled. For laser light delivery, the output of a 594-nm laser (Mambo, Cobolt) was fiber-coupled into a single-mode fiber patch cable using a 3.3-mm focal length aspheric lens and the fiber mounted on a fiber-launch translation stage (MBT616D, Thorlabs) with associated hardware for FC/APC connectors. APC angled connectors were necessary to prevent back reflections into the laser head. The coupling fiber was connected to the LFP/fiber electrode using a FC/APC-FC/APC coupler. Optical throughput of a freshly prepared LFP/fiber electrode was 60–70%, and laser power out of the LFP/fiber electrode was between 7 and 12 mW for silencing experiments.

Photodetector for in vivo intensity measurements. To determine the light intensity profile for LFP/fiber electrodes, we constructed a photodetector device that could measure local light intensities in vivo. A plug of 645-nm-emitting quantum dots (QDP-645, Ocean Nanotech) was imbedded in epoxy at the tip of a pipette. To collect quant photon flux excited by laser light, this photodetector pipette also contained a 200-µm-core, 0.22 NA fiber, etched at one end to 40 µm diameter and fully inserted and glued into the photodetector pipette (Supplementary Fig. 7a). This fiber was connected to a bandpass filter (641/75, Semrock) and fluorescence was measured using a fiber-coupled spectrometer (QE65000, Ocean Optics). For the in vivo work, the photodetector was mounted onto the same manipulator used for patch experiments and inserted in a behaving animal at the same location as a patch electrode, to record the light intensity as a function of depth from the cortical surface. The laser light intensity was also measured at several distances from the LFP/fiber electrode tip, to generate an in vivo laser intensity heat map (Supplementary Fig. 7b). The photodetector was calibrated in saline using a 200-µm-core fiber coupled to a 561-nm laser as a light source of spatially defined light intensity using the same geometry as that used in vivo.

EC3 inactivation. To inactivate EC3 inputs, we crossed mice expressing Cre in EC3 (pOxr1-cre) with mice expressing Rosa-CAG-LSL-Arch-GFP-WPRE.
In vitro electrophysiology (Fig. 3 and Supplementary Fig. 3). 400-µm transverse hippocampal slices were cut from 8- to 10-week-old male C57Bl/6 mice using a Leica Vibromate VT1200S after perfusing an isoflurane-anesthetized animal with ice-cold solution containing (in mM) 210 sucrose, 25 NaHCO3, 2.5 KCl, 1.25 Na2HPO4, 0.75 CaCl2, 7 MgCl2, 7 glucose. Slices were incubated for 30 min at 35 °C, and then recorded from at 35 °C, in a solution containing (in mM) 125 NaCl, 25 NaHCO3, 3 KCl, 1.25 Na2HPO4, 1 MgCl2, 1.2 CaCl2, and 25 glucose. All solutions contained fresh sodium pyruvate (3 mM) and ascorbic acid (1 mM), and were bubbled with 95% O2 and 5% CO2. Cells were visualized using an Olympus BX-61 microscope using a water-immersion lens (60×; 0.9 NA, Olympus, Melville, NY). Whole-cell current-clamp recordings were performed using a Dagan BVC-700 (Minneapolis, MN) in active ‘bridge’ mode and were analog-filtered at 10 kHz before being digitized at 50 kHz using Prairie View acquisition software (Bruker Technologies, Middleton, WI). The pipette solution was the same as described for the in vivo electrophysiology but also included 100 µM OGB-6f and 50 µM Alexa Fluor 594 (Invitrogen). Dual recordings were performed by first filling the soma and then target-patching the dendrite using a galvanometer-based two-photon laser scanning system (Ultima; Bruker Technologies, Middleton, WI; using Chameleon Ultra II; Coherent, Auburn, CA). Line scans for Ca2+ imaging were performed with excitation at 920 nm using a frequency of 150 Hz. Ca2+ imaging was performed in the distal apical dendritic regions because this is known to be the site of dendritic plateau potential initiation in pyramidal neurons6–11. Trains of EPSPs were elicited by electrically stimulating axons in the stratum radiatum or stratum lacunosum-moleculare using platinum–iridium alloy bipolar microelectrodes (MicroProbes, Gaithersburg, MD) placed ~100–150 µm away from the recording site.

In vitro electrophysiology (EC3 inactivation, Supplementary Fig. 8). Longitudinal slices through area CA1 of the dorsal hippocampus (400 µm) were prepared using standard procedures from 5- to 11-week-old EC3 crx × Ai35 or Ai40D male or female mice. Slices were prepared as above with the following changes to recording solutions: cutting solution containing (in mM) 197.2 sucrose, 28 NaHCO3, 2.5 KCl, 1.25 Na2HPO4, 7 MgCl2, 1 CaCl2 and 7 glucose, incubation solution contained 65.73 sucrose, 79.33 NaCl, 26 NaHCO3, 2.83 KCl, 1.25 Na2HPO4, 3 MgCl2, 1.2 CaCl2, and 19 glucose, and recording solution contained 119 NaCl, 25 NaHCO3, 3 KCl, 1.25 Na2HPO4, 1 MgCl2, 1.3 CaCl2 and 25 glucose with 2 µM SR 95531 hydrobromide (gabazine) and 50 nM CGP 55845. Trains of EPSPs were elicited by electrically stimulating path axons using a platinum–iridium alloy microelectrode (MicroProbes, Gaithersburg, MD) placed ~700–850 µm from the recording site. Theta burst stimuli consisted of five pulses at 100 Hz delivered five times with an inter-burst interval of 150 ms. Stimulus intensity was set such that the peak amplitude of the response to a burst recorded at the distal dendritic trunk was ~5–10 mV. For whole-field Arch activation in slices, broad-spectrum light from an X-Cite lamp (Lumen Dynamics, Ontario, Canada) was passed through a 55-µm-wide bandpass excitation filter centered at 590 nm and delivered through a 20x objective (Carl Zeiss, Germany), resulting in light intensities at the sample of ~30–60 mW/mm2. Data analysis. The firing fields of single neurons were determined by first dividing the length of the belt into 100 bins. For each bin, the number of APs discharged in the bin was divided by the time the animal spent in the bin in order to generate a vector of firing rates. The firing rate vector was smoothed by a running average (boxcar) of 5 bins. Periods when the mouse ran slower than 5 cm/s were removed from analysis. Neurons were considered place cells if the firing rates of a series of the adjacent bins was 0.2 of the peak for at least 20 cm (10 bins) and had a mean in-field firing rate more than 3 times the mean out-of-field firing rate.

To produce mean field firing-frequency plots for the population of place cells (Fig. 1d), the peak of the spatial firing rate distribution of each cell was centered at 100 cm (peak determined from smoothed (5-pixel Gaussian kernel) firing rate distribution). The aligned spatial firing rate distributions were normalized by dividing by the peak firing rate of each neuron and then this population was averaged to produce a single distribution. This mean normalized distribution was then binned (10 cm). Only neurons with a plateau probability >1 per 100 APs were used in this analysis, as well as for the ISI distributions shown in Figure 4c (N = 16).

To quantify the average baseline Vθ. APs were removed by deleting all points 0.26 ms before and 3.4 ms after a threshold value (dVθ/dt = 50 V/s) and baseline Vθ was defined as the peak of Vθ histograms (Vθ mode) from the resulting traces using a bin size of 0.2 mV. All traces were corrected for baseline drift on a lap-by-lap basis by determining the average deviation of the most hyperpolarized 5% of AP voltage thresholds measured from an expected value of ~50 mV. To determine the properties of plateau potentials underlying complex spiking, we used a signal detection protocol that began by smoothing the above trace with a running average (401 point, ~20 ms) boxcar procedure, following linear interpolation of the deleted AP points. Events were detected from this trace by threshold crossing (~35 mV). This value was determined as a conservative estimate of where Vθ distributions deviate from normal (Gaussian) (Supplementary Fig. 3). A second threshold level was evaluated (~30 mV) and, other than decreasing the total number of events detected by 12%, no quantitative differences were observed in any parameters. For the in vitro dual recordings, a burst of APs was classified as a plateau potential if the dendritic membrane potential corresponding to a somatic AP failed to repolarize below ~30 mV. Plateau amplitude was calculated as the difference of event peak, and the baseline Vθ plateau duration was the time between the positive-going and negative-going threshold crossings. Plateau probability was determined by dividing the total number of plateau events by the total number of APs per cell. To analyze ramps of depolarization, we low-pass filtered (<3 Hz) the raw AP-deleted traces using an FIR filter with a 200 ms Hamming window. Ramp amplitude was quantified as the difference between peak (10 cm average around the most depolarized value) and the baseline (10 cm average around the most hyperpolarized value). To analyze subthreshold Vθ oscillations, we band-pass filtered (<4–11 Hz) the raw AP-deleted traces using an FIR filter with a 200-ms Hamming window and derived the amplitude vector using the Hilbert transform. The change in theta envelope (Δtheta) was calculated in the same manner as the ramp amplitude.

The theta phase of APs and thetaθpeak were determined by first band-pass filtering the extracellular LFP in the theta range (4–11 Hz) and then deriving a vector of instantaneous phase using the Hilbert transform. The theta phase of each AP threshold crossing and thetaθpeak peak depolarization was found by interpolating from the vector of instantaneous phase. Theta-phase histograms of APs and plateaus were produced by dividing the theta cycle into 36 or 10 equal phase bins, respectively. The phase histogram of the AP and plateau events were computed for each individual neuron. Each AP phase histogram was fit by a sine function and the phase preference and modulation index were determined from the peak and modulation depth (peak – trough)/peak determined from this fit. These same values were determined for the plateau from smoothed plateau phase histograms (three-bin Gaussian window). For the population averages in Figure 2c, histograms of each neuron were first normalized by dividing by the total number of events found in each neuron. To determine whether there were any offsets in the phase of the recorded theta oscillation, in all recordings a reference LFP recording was performed at the site of the whole-cell recording simultaneous with the standard LFP recording and the theta phase peaks of the two simultaneously recorded LFP signals were compared. Most phase peak differences were less than 10° and no corrections were performed. However, differences between 10° and 40° were found in five neurons and we corrected for these differences during analysis.
(with the start location being the proximal position where rate is 20% of peak firing) was compared with the average phase of the last 10 cm of the place field (with the end location being the distal position with 20% of peak firing).

The impact of EC3 inhibition on plateau properties was characterized in place cells (N = b) where EC3 was inhibited by activating Arc within the place field on alternating laps (Fig. 3b). Average event probability (per 100 AP), duration and normalized duration (probability multiplied by duration) were determined for periods of running during which the laser shutter was opened (light) and these events were compared to those detected at the same spatial location on the belt (average position of the light periods) for control laps (no light).

The level of place field induction was quantified as the difference in the mean \( V_m \) ramp of all laps before plateau or AP initiation versus the mean \( V_m \) ramp of all laps recorded between 10 and 15 min after induction (or, for shorter recordings, the final 5 min). The \( V_m \) ramp for each lap was calculated as above. For the plots in Figure 5f,g, the data are mean ± s.e.m., with the number of neurons in each point being 3, 4, 5, 6, 6, 5, 4, 6, 6, 5, 5, 5, 3, 3, 3. For the plots in Figure 6g,h the data are mean ± s.e.m., with the number of neurons in each point being 8, 9, 14, 14, 14, 14, 14, 13, 11, 9, 9, 10, 10, 10, 10 for the plateau induction protocol and 3, 4, 6, 6, 6, 6, 6, 6, 6, 6, 5, 4, 5, 4, 4, 3, 2 for the AP induction protocol.

A non-stationary fluctuation analysis (NSFA) was performed on \( V_m \) by first aligning each trace to the center of the place field (peak of \( V_m \) ramp) and then generating a mean trace from the aligned traces for each condition (before versus after). The location of the average place field center was used for the condition where no place field firing was evident. No aligning was performed on silent cells. Next APs were subtracted as above and the intracellular theta oscillation was calculated using the band-pass filtered trace generated as above. The mean trace (Fig. 7b) was then subtracted from each lap to produce a residual trace for each lap (Fig. 7a). The trial-by-trial variance calculation was from a 2-s region centered on the peak of the place field of each lap and high-order moments calculated from the entire trace (Fig. 7c,f). A mean variance trace was also calculated using the \( V_m \) residual for each lap (Fig. 7b). To produce variance–mean plots, the variance and mean were calculated (in 500-ms bins) for each lap and then combined into a single plot that was fit by the power function \( y = mx + b \). In this case the variance was calculated from residual traces produced by subtracting the low-pass-filtered \( V_m \) (ramp \( V_m \)) from the \( V_m \) trace for each lap.

A simple simulation of random input integration was run to demonstrate the impact of changes in input unit frequency versus input unit amplitude. 300 Poisson-like interval input trains (150 excitatory and 150 inhibitory) were generated using the following function: \( n_{i+1} = n_i - \log(U/\lambda) \), where \( n_{i+1} \) is the next interval, \( n_i \) is the current interval, \( U \) is a random number and \( \lambda \) is the rate. All intervals <4 ms were excluded to mimic the AP refractory period. For standard conditions, \( \lambda \) was set to produce approximately a 20-Hz input rate per train; for the simulation shown in Supplementary Figure 14, mean interval = 48 ms, distribution decayed exponentially with \( T = 42 \), ms. Excitatory and inhibitory units were produced by convolving a ‘synaptic current’ of the form \( f(t) = a[1 - \exp(-t/\tau_f)]^3 \exp(-t/\tau_a) \), where \( a \) is a constant, \( \tau_f = 0.04 \) ms and \( \tau_a = 0.8 \) ms, with a ‘membrane filter’ that was an exponential function with \( \tau_m = 6.7 \) ms. Excitatory amplitudes were pulled from a Gaussian distribution with a mean amplitude of 0.2 mV for control conditions while inhibitory units had an mean average of ~0.2 mV. This produced inputs approximating unitary EPSP inputs recorded in CA1 neurons. A forcing function (green trace in Supplementary Fig. 14a) was used to scale either amplitude or \( \lambda \) of only the excitatory trains. Input trains were summed for 20 simulated trials and a NSFA was performed as above. The equations governing this process (Supplementary Fig. 14) show how variance is more sensitive (by the square) to changes in amplitude than rate. Overall the simulation shows that for conditions where inhibitory input rate does not increase significantly (that is, fourfold; Supplementary Fig. 14g) it is impossible to achieve the levels of \( V_m \) variance (elevations of approximately fourfold) observed in experimentally recorded place fields (with ~10 mV ramp) for this simple type of input integration model. Furthermore, even when extreme rate changes are used (sixfold excitation increase paired with fourfold inhibition increase) the relationship between \( V_m \) variance and mean is approximately linear (Supplementary Fig. 14g). By contrast, the relationship between \( V_m \) variance and mean was found to be greater than linear (power = 1.7) when the forcing function was applied to unit amplitude (Supplementary Fig. 14f).

Ripples were detected using the following algorithm. (1) LFP recordings from periods during which the animal did not run were concatenated and subsequently band-pass filtered between 100 and 250 Hz using an FIR filter. (2) The envelope of the filtered signal was calculated using the Hilbert transformation and ripples were subsequently detected as signals increasing >7 s.d. above baseline. (3) The onset and the end of the ripple were marked as the time points at which the envelope decreased below 3 s.d. of the baseline period; the time of the ripple peak was determined by peak detection between ripple onset and end. (4) The successful identification of the ripples and their features (peak, onset and end) was confirmed through visual inspection of the filtered signals along with the raw LFP signal. \( V_m \) periods during ripples were subsequently further analyzed. The number of APs during a ripple was determined by the number of threshold crossings in the corresponding \( dV_m/dt \) trace (threshold = 50 V/s). Smoothed \( V_m \) traces (as above) were used to analyze ripple-associated subthreshold \( V_m \), \( \Delta V_m \) was calculated as the difference between the mean \( V_m \) values centered ±10 ms around the ripple peak and the baseline \( V_m \). For each lap, the baseline \( V_m \) value was determined by the peak of the \( V_m \) histogram (see above).

For the analysis in Figure 8 (N = 16 neurons), the neuron’s place field was determined using the subthreshold slow \( V_m \) depolarization (or ramp), which is a typical intracellular feature of place fields20. To quantify the ramp, the linear track was divided into 100 spatial bins (each 1.9 cm wide) and an average \( V_m \) value was calculated for each bin using the previously generated AP-deleted \( V_m \) trace. After calculating the mean ramp depolarization across all laps, the place field was defined as locations on the linear track where the average of the subthreshold ramp continuously exceeded a baseline period (determined by visual inspection) of about 10 neighboring bins (>19 cm) for at least 5 adjacent bins (9 cm). The remainder of the linear track was considered to be outside the place field. These place fields covered on average 74 ± 2% (mean ± s.e.m.) of the linear track. Ripple location was calculated relative to the midpoint (place field center) between place field start and end. Locations before and after the place field center were pooled.

Statistical methods. No statistical methods were used to predetermine sample sizes, but our sample sizes are similar to or larger than those reported in previous publications19–21. Where appropriate, data were analyzed using two-tailed paired or unpaired t-tests. Plateau duration, amplitude and probability are shown in text to be normally distributed. We assumed the same for ramp and theta amplitudes. If normality was uncertain, we used non-parametric test as stated in the main text or figure legends. All manipulations were done within single neurons, with manipulations interleaved trial-by-trial (light versus no light) or in blocks of five trials (current injections). Data were analyzed automatically without consideration of trial condition. To determine whether plateau counts displayed location dependence (Fig. 4c), locations were shuffled 10,000 times, resulting histograms were fit with a Gaussian and \( R^2 \) values were compared between data histogram and location-shuffled data (bootstrapped permutation test). Data are shown as mean ± s.e.m. Data collection and analysis were not performed blind to the experimental conditions.

A Supplementary Methods Checklist is available.
CA1 pyramidal neuron firing categories.

From top, Vm (black) and LFP (green) traces for sequential laps as a function of time, trial-by-trial AP spatial firing rate, mean AP spatial firing rate, mean ramp depolarization, mean theta envelope as a function of position from neurons categorized as a, silent cells, b, non-place cells and c, place-cells.
Supplementary Figure 2

Place field firing and theta phase procession.

a, Top. AP rate for single trials as a function of distance for a representative cell (neuron#1 from 1d). Bottom. Average AP rate as a function of distance for all trials. b, Representative intracellular Vm as a function of time for consecutive trials for cell shown in a. c, (from top) ramp potential for lap#20 of neuron#1 (red); intracellular theta (\( \theta_{in} \), blue), envelope of \( \theta_{in} \) (envel., black); the mean ramp trace versus position for all laps (red), amplitude calculation shown; the mean envelope trace versus position (black) with \( \Delta \theta \) calculation shown. d, Top, Hilbert transform of extracellular theta as a function of time (grey). Colored dots represent
phase of APs (black) and intracellular theta peaks (blue, theta-in). Bottom traces are extracellular theta (green), intracellular theta (blue), and intracellular Vm (black) as a function of time. Data are from lap 20 for cell shown in a. e, Theta phase of all APs (black) and intracellular theta peaks (blue) for lap 20 as a function of time. f, Extracellular theta phase of intracellular theta peaks (left) and APs (right) for all trials as a function of position. Individuals are shown in grey and boxcar smoothed data are shown in colored (5 points). g, Extracellular theta phase of intracellular theta peaks (blue) and APs (black) as a function of position for all trials binned in 10 cm bins for cell shown in a. Grey dotted line is a Gaussian fit to the place field and plus symbols represent first and last 10 cm of the field (10 cm bins). h, Extracellular theta phase of intracellular theta peaks (theta-in, blue) and APs (black) as a function of position for all place cells (N=14). Data are shown as mean±SEM for the first and last 10 cm and these points were used to test for significance; p=0.2e⁴ for theta-in and p=0.1e⁻⁵ for APs paired two-way t-test.
**Supplementary Figure 3**

**Plateau potential detection and characterization.**

**a,** Representative intracellular Vm as a function of time. Dotted lines indicate plateau threshold (-35 mV) and baseline Vm (-60 mV). Right trace is expanded (black bar).

**b,** Intracellular Vm from cell in a with spikes removed and smoothed (smoothed Vm) as a function of time. The smoothed Vm trace was used for automatic detection of plateau potentials. Arrows indicate detected plateau events. Right trace is expanded (black bar).

**c,** Frequency distribution of smoothed Vm for all laps of cell in **a** (red). Distribution fit by double gaussian function (black), with separate peaks labeled. Expanded plot (inset) shows prominent tail diverges from fit near -35 mV for this cell with a high plateau probability (9.2/100 AP).

**d,** Frequency distribution of smoothed Vm for all laps of cell shown in Fig6a-f (red). Distribution fit by double gaussian function (black), with separate peaks labeled. Expanded plot (inset) shows no prominent tail for this cell with a low plateau probability (0.7/100AP).

**e,** Vm distribution for all cells showing plateaus (N=9) separated into trials containing plateaus (black) and those without plateaus (red) demonstrating non-gaussian tail component is due to the occurrence of plateau potentials. Arrow indicates location of baseline Vm. Inset in e shows distribution over a smaller Vm range.

**f,** left, Experimental setup for *in-vitro* data in f-k. Dual (soma and dendrite) recording of a CA1 neuron. Bipolar stimtrodes were placed in SLM and SR, approximately 100 µm from the recording site (not shown). Right, Representative somatic Vm (black), dendritic Vm (blue) and smoothed Vm (red) in response to electrical stimulation (artifacts removed during analysis).

**g,** FWHM for the last spike in the AP burst recorded at the dendrite with classification for plateaus as described in methods, example shown at top.

**h, i,** Distribution (h) or cumulative distribution (i) of peak smoothed Vm for plateau (red) and non-plateau (black) AP bursts. Plateaus were identified from dendritic voltage.

**k,** Vm distribution for all cells with (red) and without (black) plateaus (N=7).
Plateaus are positively correlated with firing rate, ramp amplitude and Δtheta.

a, b, Representative intracellular Vm traces (a) and spatial firing rates (b) for 4 laps from a representative cell. c, f, Subthreshold Vm low-pass filtered to produce ramp traces (e) and band-pass filtered to produce intracellular theta traces (theta_{in}, grey, f) and envelope (blue, f) from 4 laps shown in a. g, h, i, Plateau probability as a function of peak firing rate (g), ramp amplitude (h), and Δtheta (i) for all place cells (N=22).
**Supplementary Figure 5**

**MK801 decreases plateau probability and duration.**

a, b, c, d Average AP rate (a), plateau probability (b), plateau duration (c), and plateau probability*duration (d) for control cells (black, open symbols, N=17) and MK801 containing cells (red, open symbols, N=13 for probability, n=10 for duration). Filled symbols are population averages shown as mean±SEM. Plateau probabilities and durations were calculated for all cells over the entire duration of the recording over both running and non-running periods using a threshold of -30mV. Only recordings of 15 minutes or longer were included in the analysis to ensure complete dialysis of cell with 1-2 mM MK801. The control cells included here were all stable recordings of greater than 15 minutes in length that were recorded within 9 months of the MK801 cells. Asterisks indicate p=0.0016 for probability and p=0.009 for normalized duration, Mann-Whitney U test.

Supplementary Figure 6

Manipulation of AP phase using LFP current injections.

Schematic of manipulation to examine the effect of CA1 spike phase on plateau probability. Briefly, the extracellular LFP was filtered, phase shifted and injected into the cell as a current. The current was phase shifted sufficiently to cause spikes to occur near the peak, (short delay, red, center) or trough (long delay, blue, right) of extracellular theta. b, c Online LFP processing to produce current injections that result in spiking at the peak of extracellular theta (red, b) or the trough of extracellular theta (blue, c). d, e, Representative intracellular Vm traces (d) and smoothed intracellular Vm (e) without current injections (black), with injected current with short delay (red, peak), or with injected current with long delay (blue, trough).
**Supplementary Figure 7**

Optical delivery and light intensity measurements.

a, Left, Composite image of the photodetector taken in brightfield (grayscale image) and fluorescence (red image, 561 nm excitation, 630/75 emission), showing the region of 645-nm emitting quantum dots at the end of a pipette tip; Center, Diagram for 594 nm laser light delivery via an optical fiber to a LFP/fiber electrode (black), and detection of laser light via induced quantum dot fluorescence from the photodetector pipette (magenta) recorded by a fiber-coupled spectrometer (not shown), this geometry was used for both *in vivo* measurements and intensity calibration in saline; Right panel: Representative LFP/fiber electrode with 8.5 μm diameter etched fiber, recessed 200 μm from the pipette tip.  

b, Laser intensity measurements taken at 50 μm steps in the vertical direction and 100 μm in the saggital plane represented as a heatmap with 50 μm pixels. Pixel values between lateral data points were linearly interpolated and superimposed on a DAPI stained saggitally sliced 150 μm thick section, intensity scale is for 1 mW power out of the LFP/fiber electrode with fiber tip recessed 90 μm from pipette tip.  

c, Representative LFP recording (blue) from an EC3xAi35D to show the effect of light (594 laser pulses, yellow lines) on the LFP in Arch expressing mice. In Arch positive mice there was a reproducible DC offset in the LFP induced by light that did not occur in mice not expressing Arch.  

d, Representative LFP (blue) and intracellular Vm (black) traces from a C57/B6 mouse during light pulses (yellow) to demonstrate a lack of effect of the light in mice not expressing Arch.
Supplementary Figure 8

Light stimulation of Arch in EC3 axons in CA1 in hippocampal slices reduces evoked perforant path EPSPs.

a, Example 2-photon Z-stack of a CA1 neuron patched at the soma with Alexa Fluor 488 dye in a hippocampal slice from a mouse expressing Arch-EGFP in EC3 axons. b, Example voltage trace from a CA1 soma during theta burst electrical stimulation of perforant path axons in the presence and absence of whole-field red light (590/55nm) stimulation to activate Arch expressed in EC3 axons. c, Summary of experiments of the type shown in (b). The average EPSP area is expressed as mean ± SEM (N=8, p=0.015, Mann Whitney U-test paired).
Supplementary Figure 9

Effects of light on intracellular \( V_m \) in an EC3xAi35D mouse.

a, b, Representative intracellular \( V_m \) (a), and smoothed intracellular \( V_m \) (b) as a function of position for consecutive trials with (yellow) and without (black) light pulses from a representative cell in an EC3xAi35D mouse. The light pulses are shown in grey and the blue dotted lines indicate the relative location/time of the light pulses. Control trials for this cell had 12 plateaus and 476 APs while light trials had 1 plateau and 285 APs. Plateau probability was 2.5/100APs for control and 0.4/100APs for light trials. Average durations were 91 ms (control) and 50 ms (light) and total durations were 228 (control) vs 20 (light) ms/100APs. c-e Peak firing rate (c), Δtheta (d) and ramp amplitude for all cells (N=8) for control (grey) and light (yellow) periods. Individuals are shown colored and averages are in black as mean±SEM.
Supplementary Figure 10

Place fields induced by spontaneous plateau potentials.

a, AP firing rate as a function of position for single laps for all cells in which a place field formed after a spontaneous plateau potential. The lap containing the plateau is indicated with an arrow. b, Representative intracellular Vm as a function of time from laps with spontaneous plateaus.
Supplementary Figure 11

Place fields formed following plateau-inducing current injections. 

a, b, c, AP firing rate as a function of position for single laps for all cells in which a place field was induced using current injection at position 1 (a), position 2 (b) and position 3 (c). The laps containing the current injections are marked with an arrow. b, d-f, Place field (e), AP (f) and plateau (d) properties for naturally occurring place cells (C, N=21) or place cells induced using plateau current injections (I, N=14). d, Plateau theta modulation (left) and theta phase preference (right). e, Intracellular Vm ramp (left), Δtheta, (middle) and phase precession (right). f, Left to right, AP peak rate, AP theta phase preference, and AP theta phase precession. Data are shown as mean±SEM (d-f). p-values from left to right are 0.068, 0.079, 0.46, 0.001, 0.09, 0.22, 0.28, 0.067; unpaired two-tail t-tests.
Supplementary Figure 12

$R_m$ does not change following place field induction.

a, Representative current waveforms and resulting $V_m$ deflections for times b, before and c, after the place field induction. Average voltage deflections from entire sequence used for $R_m$ calculation are shown at right. d, plot of $R_m$ versus time for entire recording. Values calculated from traces in b and c are indicated. e, population data for all neurons with induced fields (N=14).
Supplementary Figure 13

APs alone do not induce place fields.

a, Representative intracellular Vm as a function of time for laps (numbers at left) before, during and after current injections that induce APs but no plateaus. Current injections were 100 Hz, 2 ms pulses for at least 300 ms. b, AP firing rate for single laps as a function of distance for representative cell from a. Arrow indicated where currents were injected c, Top, intracellular Vm (black), and extracellular theta (green) from lap 10 as indicated by red box on expanded time base to show plateau characteristics. Red line is smoothed trace. Bottom, the trace from top shown on an expanded time base to show AP characteristics. d, Mean intracellular ramp amplitude (top) and Δtheta (bottom) as a function of time for cell in a. e, Average intracellular ramp (top) and theta (bottom) as a function of time across laps within the time window indicated by the grey or black bar in d to show the average ramp and theta for laps before and after current injections (N=6).
Supplementary Figure 14

Integration of Poisson input trains simulation.

**a**, Model EPSPs for a single excitatory input train with a 3x increase in amplitude (black) or rate (grey) within the field with no change in IPSP rate or amplitude (red). Forcing function for amplitude or rate (green). **b**, model Vm as a function of time for 300 inputs (150 excitatory, 150 inhibitory) for a single lap and corresponding residual. **c**, residual probability distribution outside the field (blue), in field with an increase in rate (grey), or amplitude (black). **d**, mean Vm (top) and variance (bottom) for a change in rate (grey) or amplitude (black). **e**, Variance as a function of trial out of field (blue), in field with a change in rate (grey), or amplitude (black). **f**, variance as a function of mean for a change in rate (grey) or amplitude (black). Lines are fits by $y=m^p x+b$, where $p$ for each condition is shown. **g**, variance as a function of mean for an extreme change in both excitation rate (6X) and inhibition rate (4X). Lines are fits by $y=m^p x+b$, where $p$ is shown. Bottom, equations governing the linear integration of Poisson EPSP and IPSP input trains.

**Supplementary Figure 15**

Schematic of hypothesized impact of nonlinear input processing on feature-specific firing.

**a,** Generalized cortical microcircuit. 1) Pyramidal type principal neuron, 2) separate feed forward inhibitory elements, 3) dendrite targeting feedback inhibitory element, 4) disinhibitory elements with modulatory input. **b,** No feature specific firing for a given context occurs when the neuron receives many hundreds of weak excitatory inputs each with their own feature selectivity when this input is countered by nonselective inhibitory inputs. **c,** To induce feature specific firing a plateau is initiated by matched EC3 and CA3 input plus some disinhibition and the excitatory input associated with the plateau potentiates. **d,** feature specific firing is expressed and maintained in a given context when the potentiated inputs depolarize the neuron at the feature position. Evoked plateaus maintain potentiation and stabilize firing field. **e, i)** CA1 microcircuit involving pyramidal neuron #10 receives input from EC3 but only weak or phase delayed input from CA3 leading to **ii)** linear (no plateau initiated) dendritic integration between input streams that **iii)** does not induce synaptic/dendritic plasticity leaving the input with a low efficacy and **iv)** a low frequency single spiking output. **v)** If a place field is generated in this neuron it is weak and unstable leading to **vi)** the unique context-dependent population activity map using both rate and phase coding. **f,** scheme for processing in hypothetical context #2. **i)** CA1 microcircuit involving pyramidal neuron #10 receives input from EC3 with strong or phase advanced input from CA3 leading to **ii)** nonlinear (plateau initiated) dendritic integration between input streams that **iii)** induces strong synaptic/dendritic plasticity leaving the input with a high efficacy and **iv)** a high frequency burst firing output. **v)** The place field generated in this neuron is strong and stable leading to **vi)** the unique context-dependent population activity map using both rate (shown) and phase coding. Same neurons and spatial alignment as in context #1. EC3 and CA3 input are labeled with hypothetical informational content that could produce episode specific memories.
